buffer. Mixtures of riboflavin and pyridoxine in infant formula products can be determined simultaneously using ion-pair LC with fluorescence detection.

Fluorimetric LC methods for the determination of fat-soluble vitamins in foods have been described for vitamins A (retinol), E, and K. These methods usually entail saponification and extraction steps. The determination of vitamin A, which shows intrinsic fluorescence, in foods containing large amounts of carotenoids, requires chromatographic purification. This technique has also been used in studying the extent of vitamin A isomerization during manufacture and storage of liquid and dried milk products, which involves prior isolation of the different isomers using LC.

Estimation of true vitamin E in foods requires quantitative determination of all its components since they vary in their biological potency. This vitamin consists of four tocopherols ( $\alpha$ ,  $\beta$ ,  $\gamma$ , and  $\delta$ ) and four tocotrienols ( $\alpha$ ,  $\beta$ ,  $\gamma$ , and  $\delta$ ), but the three major constituents responsible for vitamin E activity are the  $\alpha$ -,  $\beta$ -, and  $\gamma$ -tocopherols. While these compounds are fluorescent, their esters must be reduced to free alcohols for total tocopherol assays. Total vitamin E can be directly obtained through fluorimetry, but the determination of individual components is carried out using LC with fluorimetric detection. This procedure has been used to determine the composition of vitamin E in seed oils from maize, olives, soya beans, sesame, safflower, and sunflower by measuring the content of all the four tocopherols plus  $\alpha$ -tocotrienol. The simultaneous determination of tocopherols, carotenes, and retinol in cheese has been carried out using LC with two programmable detectors connected in series, a spectrophotometer and a fluorimeter. Carotenes have been determined photometrically, and fluorimetric measurements have been obtained for tocopherol and retinol.

The vitamin K group is usually determined in foods such as fats, oils, and milk through LC with fluorimetric detection after postcolumn zinc reduction. Samples are usually digested with lipase and extracted into hexane.

### Proteins, Peptides, Amino Acids, and Amines

Proteins in foods such as milk have been the subject of much fluorimetric study involving measurement of the intrinsic fluorescence of tryptophan and tyrosine; however, since proteins vary in their content of these amino acids, the fluorescence intensity also varies markedly from protein to protein and, for a single protein, with the experimental conditions. Also, the natural fluorescence of peptides is limited to peptide-containing tryptophans and tyrosines. However, the joint use of LC and derivatizing fluorogenic agents such as dansyl chloride, ninhydrin, fluorescamine, and *o*-phthaldialdehyde (OPA) has allowed the development of a number of methods for the determination of proteins, peptides, amino acids, and amines in food samples.

Dansyl chloride has the disadvantage that any excess of reagent or its degradation products must be removed before the derivatives can be chromatographically separated. Ninhydrin derivatives are reportedly superior and lend themselves readily to automated use. Because ninhydrin is not fluorescent, any excess remaining in solution poses no interference, but the derivatization process involves some heating. Fluorescamine reacts very rapidly at an alkaline pH with primary amino groups giving rise to fluorescent derivatives and can be used in either aqueous solutions or organic solvents; however, the fluorescence yield of its derivatives is ~10 times lower than those of OPA derivatives. Peptide determination methods involving LC have been described using pre- or postcolumn derivatization with fluorescamine. OPA is a highly versatile reagent, even though it does not react with proline or hydroxyproline, and gives a very weak fluorescence with cysteine. It reacts rapidly with primary amino groups at pH 9–11 in the presence of a thiol such as 2-mercaptoethanol (2-ME), 3-mercaptopropionic acid, 3-mercapto-1-propanol, or ethanethiol, yielding is-indole fluorescent derivatives. OPA has been widely used as a derivatizing reagent in food analysis using LC separations. For instance, through precolumn derivatization, polar amino acids are converted into hydrophobic compounds that can be rapidly separated on a reversed-phase column. The amino acids can also be isolated on an ion-exchange column, followed by postcolumn derivatization. It has also been used to determine peptidase activity, based on the

fact that the fluorescence yield of the OPA derivatives of peptides is much lower than it is for amino acids. Some methods for peptide determination in foods involve the use of OPA fluorescence detection online coupled with absorbance detection. The usefulness of this coupling for obtaining additional information has been shown for the selective determination of peptides in blue cheeses and skimmed milk.

Some fluorimetric methods for the individual determination of amino acids in foods have also been reported. Thus, the native fluorescence of tryptophan has been used for its determination in food and feed hydrolysates using ion-exchange chromatography. Also, 3-methylhistidine has been determined in meat and meat products using LC and precolumn derivatization with fluorescamine or postcolumn derivatization with OPA and 2-ME.

Although the use of CE in food analysis is limited compared with LC, many applications have been reported in recent years in the study of food proteins and peptides. It has been shown that the sensitivity provided by CE using LIF detection for bovine whey proteins is twice as good as that provided by UV detection, under the same separation conditions. LIF detection has also been used together with affinity interactions to enhance the detection sensitivity in CE. For instance, an immunoassay detection method has been described using a polyclonal antibody marked with fluorescein to determine lactoferrin. CE–LIF has also been applied to the determination of amines and amino acids in several samples such as wine and milk products.

The usefulness of kinetic methodology together with a long wavelength fluorophor has been shown for the determination of gliadins and caseins in foods. These methods involve the use of a cationic (Cresyl Violet) or anionic fluorophor (Indocyanine Green) in the presence of an anionic (sodium dodecyl sulfate) or cationic cetyltrimethylammonium bromide (CTAB) surfactant, respectively. The variation of the fluorescence intensity with time is the result of ionic forces between oppositely charged molecules, which depend on the protein concentration. These methods combine the temporal and spectral discrimination of the analytical signal, which allows the required selectivity to be obtained.

One of the few reported uses of fiber-optic biosensors in food analysis in combination with flow injection analysis is the determination of L-glutamate in soups and sauces. This amino acid plays a central role in the oxidative determination of other amino acids and is capable of sensitizing gustatory nerves. Although glutamate occurs naturally in some foods, it is also used as a flavor enhancer. The biosensor was

an oxygen-sensitive optrode with immobilized glutamate oxidase and decacyclene, being the fluorescence of decacyclene. The fluorescence of decacyclene is markedly dependent on the oxygen concentration.

Histamine in foods is primarily the result of microbial decarboxylation of histidine, and so it is a customary constituent of fermented foodstuffs such as wine and cheese, and foods with a fairly high histidine concentration (e.g., tuna fish) that have been exposed to microbial degradation. It is routinely determined in foods using fluorimetric methods involving condensation with OPA. Second-derivative synchronous fluorescence spectrometry has also been used for the direct quantification of histamine in wine and canned tuna.

### Inorganic Species

Although metal ions in foods are usually determined using atomic absorption spectrometry, there are a few fluorimetric methods based on the formation of fluorescent complexes. Thus, very low concentrations of selenium in milk, eggs, cheese, meat, and vegetables can be determined using an official method (AOAC 974.15) that involves the use of 2,3-diaminonaphthalene as a reagent. The fluorescent piazselenol formed is extracted into cyclohexane using ethylenediaminetetraacetic acid as a masking agent. Aluminum has been determined in various foodstuffs and tap water using different fluorimetric ligands such as Calcon and 2,4-dihydroxybenzaldehyde iso-nicotinoylhydrazone.

Zinc is determined in milk using an indirect kinetic fluorimetric method based on its activating effect on the Mn(II)-catalyzed oxidation of 2-hydroxybenzaldehyde thiosemicarbazone by hydrogen peroxide. The Mn(II)-catalyzed oxidation of a similar reagent, 2-hydroxynaphthaldehyde thiosemicarbazone, by hydrogen peroxide has been exploited for the kinetic fluorimetric determination of the latter in various types of coffee, tea, and milk. Another application of kinetic methodology in fluorimetric food analysis is the determination of iodide in table salt and milk using its catalytic action on the Ce(IV)–As(III) system, which involves measurement of the fluorescence of the Ce(III) formed and uses the stopped-flow mixing technique for automatic implementation.

## Determination of Food Contaminants

### Polycyclic Aromatic Hydrocarbons

These compounds are primarily found in smoked foodstuffs and roasted products including malt and

coffee as they arise from combustion of some organic materials. Since PAHs with rigid, extensively conjugated structures exhibit strong native fluorescence, they are largely determined fluorimetrically. LC coupled to a spectrofluorimeter detector is a powerful technique used widely for the determination of PAHs in foods. In this sense, benzo[*a*]pyrene is the PAH most commonly present in contaminated foods and hence that is most frequently analyzed for.

Owing to the typical complexity of the sample matrix, the fluorimetric determination of PAHs in foodstuffs entails extraction with *n*-hexane, cyclohexane, or acetone–toluene, either directly or, usually, after alcoholic–alkaline saponification. The residue is cleaned up on a column packed with silica gel, Florisil, or Sephadex, and the eluted fraction containing the PAH is analyzed using LC with, usually, acetonitrile as the mobile phase. Both isocratic and gradient elution have been described. The best way of resolving a mixture of PAHs in the eluate is through programmed fluorescence detection, i.e., use of variable excitation and emission wavelengths. An LC method for the determination of 16 PAHs in different nonfatty foods has been proposed using a gradient of acetonitrile–water as the mobile phase, together with a program of 10 excitation and emission wavelength pairs. LC with fluorimetric detection has been used widely to analyze a variety of foodstuffs (smoked foods, edible vegetable oils, shellfish, coffee, tea, malt, cereals, mineral water, spices, herbs) with good recoveries and very low detection limits (of a few nanograms per kilogram). A method proposed for the individual determination of benzo[*a*]pyrene in foods involves treatment of the sample with sodium sulfate, extraction into *n*-hexane/ethyl ether and cleanup with alumina. Phenanthrene derivatives have been determined in wood smoke from a food-smoking compartment by injecting the sample, after extraction and cleanup, into a gas chromatography (GC)–mass spectrometry system, but the detection limit thus achieved can be lowered 10-fold for benzo[*a*]pyrene using the Shpol'skii low-temperature fluorescence technique.

Fluorodensitometry has been used fairly regularly for the determination of PAHs in foods after separation using thin layer chromatography (TLC). Although the resolving power of this technique is lower than that of LC, it provides similar detection limits. There is an official method (AOAC 991.06) in which PAHs are extracted from the food sample after saponification with alcoholic KOH, purified using solvent partition and column chromatography, separated using TLC, determined using UV spectrophotometry, and confirmed using spectrofluorimetry.

## Mycotoxins

There are probably a few hundred mycotoxins, encompassing a wide range of structural and chemical types, although only a limited number occur frequently at significant concentrations in foods. These compounds are secondary metabolites produced by molds (fungi) that have a toxic effect on man and/or animals. Many mycotoxins show native fluorescence, so that the fluorescence of fungal materials is frequently used in screening raw materials in order to reject contaminated items or batches.

An important group of mycotoxins is formed from aflatoxins, which are produced by some *Aspergillus* varieties and occur in many crops used as food and animal feed ingredients, particularly grains and nuts. The aflatoxins more frequently analyzed are B<sub>1</sub>, B<sub>2</sub>, G<sub>1</sub>, and G<sub>2</sub>, which are highly fluorescent as they have a highly conjugated five-ring cyclic structure. In fact, their names are based on their fluorescent color (B for blue and G for green). TLC with fluorimetric detection has been used extensively for aflatoxin determination as there are several firmly established official methods based on this technique (AOAC 982.25, 993.17, and 998.03). There is also a similar official method for the determination of sterigmatocystin (AOAC 973.38), which is a precursor of aflatoxins. However, the present trend is the use of LC with fluorimetric detection using normal or reverse-phase methods. A limitation of this approach is the fluorescence dependence of these compounds on the composition of the solvent. For instance, the fluorescence of aflatoxins B<sub>1</sub> and B<sub>2</sub> is markedly quenched by solvents frequently used in normal-phase LC. Also, the use of reversed-phase LC is limited by the fact that the fluorescence of aflatoxins B<sub>1</sub> and G<sub>2</sub> is quenched in aqueous medium.

Several derivatization procedures have been proposed to circumvent these shortcomings, involving the use of trifluoroacetic acid (TFA), iodine, bromine, or pyridinium bromide perbromide. TFA transforms aflatoxins B<sub>1</sub> and G<sub>1</sub> into their highly fluorescent hemiacetals, B<sub>2a</sub> and G<sub>2a</sub>, while aflatoxins B<sub>2</sub> and G<sub>2</sub> are not affected by this reagent due to their saturate structure. A limitation of TFA derivatization is the low stability of the products in methanol, probably due to the formation of methyl acetals. Official methods for aflatoxin determination in several foods are based on TFA precolumn derivatization (AOAC 990.33 and 994.08). One of these methods involves the use of a multifunctional column containing a mixture of reverse-phase, ion-exclusion, and ion-exchange sorbents, which retain interfering substances such as fats, proteinaceous compounds, pigments,

**Table 1** Performance characteristics for aflatoxin determination using LC with fluorimetric detection

Aflatoxin	Matrix	Dynamic range (ng per g)	Recovery (%)	RSD <sup>a</sup> (%)
Total	Almonds	5–30	116	16
	Brazil nuts	5–30	97–140	9
	Corn	5–30	98–102	6–20
	Peanuts	5–30	74–91	7

	Peanuts	1–3	93–101	14
	Pistachios	1–3	76–80	21–27

<sup>a</sup>RSD, relative standard deviation.

and carbohydrates extracted from food and feed ingredients. Aflatoxins are eluted from the column, derivatized with TFA, and quantified using LC with fluorescence detection. **Table 1** shows some features of the application of this method to several samples. The availability of automated LC systems with post-column derivatization is preferable for reducing the manipulations required for each sample. However, the use of TFA for postcolumn derivatization is limited because of its toxicity and its corrosive properties on the pumping devices. Alternative postcolumn derivatization methods have been proposed. Thus, aflatoxin hemiacetals have been generated with post-column in-line photochemical UV irradiation, which can be detected at subpicogram levels using LIF. Also, postcolumn derivatization with iodine has been adopted as an official method (AOAC 991.31), which involves the use of an immunoaffinity column containing an immobilized antibody to aflatoxins B<sub>1</sub>, B<sub>2</sub>, G<sub>1</sub>, and G<sub>2</sub>, in which aflatoxins are isolated, purified, and concentrated before their LC separation.

In addition to aflatoxins, there are other mycotoxins that can be determined fluorometrically. Official methods have been established for deoxynivalenol (AOAC 986.17), ochratoxin A (AOAC

973.37 and 991.44), zearalenone (AOAC 985.18), and fumonisins (AOAC 995.15), using TLC or LC and fluorescent detection. All these compounds exhibit native fluorescence, except fumonisins, which require a previous derivatization step using OPA and 2-ME.

The usefulness of immunochemical techniques for the fluorimetric determination of mycotoxins has been widely demonstrated. In addition to the use of immunoaffinity column cleanup followed by LC with fluorescent detection, several FIAs have been described for the determination of aflatoxins, deoxynivalenol, and fumonisins using fluorescence polarization immunoassay or time-resolved fluoroimmunoassay. Also, although the application of fluoroimmunosensors to food analysis has been relatively limited, there are some examples of the use of this approach to the determination of some mycotoxins such as aflatoxin B<sub>1</sub> and fumonisin B<sub>2</sub>.

### Phycotoxins

Phycotoxins, also named shellfish toxins, are produced by free-living micro-algae upon which the shellfish feed. The toxins are concentrated in the shellfish, which act as a vector transferring the toxic compounds to the food chain. Control of the presence of these toxins in food is required as they can cause neurotoxic, diarrhetic, paralytic, or amnesic poisoning. LC methods with fluorescence detection are now available for the determination of some of these compounds, such as domoic acid, saxitoxins, okadaic acid, and ciguatoxins. Also, an enzyme inhibition assay has been described for the determination of okadaic acid in mussels using fluorescent endpoint detection.

### Nitrite, Nitrate, and Nitrosamines

The nitrate content in foods of animal and plant origin is significant because nitrate can be reduced to nitrite, which reacts with hemoglobin to form methemoglobin. Nitrite can also react with secondary amines to form *N*-nitroso compounds, which have been shown to be carcinogenic, mutagenic, and teratogenic. While volatile dialkyl nitrosamines are amenable to determination using GC, nonvolatile derivatives are commonly assayed using LC. Thus, *N*-nitrosopyrrolidine, which has been detected at the nanogram per gram level in fried bacon, is determined using LC with fluorimetric detection. The nitrosamine is treated with hydrogen bromide in acetic acid, and the resulting amine is derivatized with 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole to give a

highly fluorescent product that is injected into the chromatographic system. Nitrosamines can also be extracted from foods with ethyl ether, reduced to secondary amines with Ni–Al alloy, and derivatized with fluorescamine.

Very low concentrations of nitrite in milk have been determined through the formation of 1-[*H*]-naphthotriazole using 2,3-diaminonaphthalene as a reagent. Another fluorimetric method for nitrite determination in cured meat products relies on diazotization of 2-aminophenol and coupling with resorcinol. The resulting 2,2',4-trihydroxyazobenzene derivative is reacted with gallium to give a strong orange-red fluorescence. Nitrate can also be determined fluorimetrically in tap water by reaction with 2-phenylbenzothiazole.

### Pesticide Residues

Pesticide residues in foods are basically determined using GC, although this technique shows some limitations for some pesticides. For instance, in the case of *N*-methylcarbamates, most of them are either retained on the chromatographic column or decomposed to their corresponding phenols. Also, GC derivatization procedures for the determination of aromatic carbamates with electron-capture detection, which involve initial hydrolysis to the corresponding phenols or amines and reaction with halogen-rich reagents, are often subject to some limitations that can detract from their sensitivity and applicability. LC procedures are reportedly more convenient than GC procedures for a wide range of carbamates, both in uncombined form through UV detection or after derivatization, usually with OPA and 2-ME, through fluorescence detection. There is an official method (AOAC 985.23) based on this approach that is applicable to residues of aldicarb, bufenarb, carbaryl, carbofuran, methiocarb, methomyl, oxamyl, and the metabolites aldicarb sulfone and 3-hydroxycarbofuran in grapes and potatoes. Some features of these methods are summarized in Table 2. LIF detection has been employed to quantify *N*-methylcarbamates through LC after precolumn derivatization with 7-chloro-4-nitrobenzoxa-1,3-diole.

Substituted ureas, such as phenylureas, are generally determined using LC, as they can be degraded to isocyanates in GC. Although detection is usually through UV absorption, phenylurea residues in various foods including maize and some vegetables and fruits have also been determined through postcolumn UV photolysis and OPA derivatization.

Several pesticides have been determined by measuring the fluorescence of their hydrolysis products after chromatographic separation. Figure 2 shows

the products obtained for the pesticides guthion, coumaphos, and zinophos. This procedure has been used to quantify guthion and coumaphos in milk and zinophos in vegetables. The intrinsic fluorescence of some pesticides allows their direct determination

**Table 2** Analytical performance of some high-performance liquid chromatography (HPLC) methods with an OPA-2ME derivatization reaction for carbamate pesticide determination

Analyte	LOD (ng ml <sup>-1</sup> )	Sample	Recovery (%)
Aldicarb	10	Potatoes	91–93
Bufencarb	10	Potatoes	96–98
Carbaryl	10	Vegetables	85–90

	20	Potatoes	90–94

without the need for derivatization. Thus, the fungicides thiabendazole and carbendazim have been simultaneously determined using derivative synchronous spectroscopy in vegetable samples with no cleanup.

Although the use of FIAs for the determination of pesticide residues in food analysis has been relatively limited, there are some examples of their suitability in this analytical field, as Table 3 shows. Various fluorescence polarization immunoassay (FPIA) methods involving equilibrium or kinetic measurements have been described for the determination of several pesticides. A homogenous FIA has been developed for the determination of 2,4,5-T using Cresyl Violet as the label, which allows long-wavelength measurements to be made in order to avoid background fluorescence signals. This pesticide has also been determined using enzyme-linked immunosorbent assay (ELISA) using a fluorogenic substrate of horseradish peroxidase.

### Veterinary Drug Residues

Fluorescence spectroscopy is frequently used in the control of pharmaceutical residues in foods, such as

**Figure 2** Hydrolysis reaction of some pesticides giving fluorescent products.

antibiotics, as they are usually used for veterinary purposes and, sometimes, as animal feed additives, so that there is a risk that residues of these drugs may be present in edible tissues. Numerous methods for the determination of tetracyclines, aminoglycosides,  $\beta$ -lactams, and fluoroquinolones have been described using LC with fluorimetric detection. **Table 4** shows some derivative reagents used for this purpose. In the case of fluoroquinolones, they are detected by measuring their native fluorescence.

Although the application of CE-LIF to this analytical field is still limited, there are some examples, such as the determination of tetracycline, oxytetracycline, and chlortetracycline in milk samples based on the formation of the corresponding fluorescent chelates with magnesium ions.

## Microbial Contamination

Fluorimetry has been used to check for microbial contamination in foods such as eggs and dairy products. This technique is of use in detecting organisms that produce fluorescent pigments (e.g., *Pseudomonas fluorescens*). For example, pyoverdine is a brilliantly green fluorescent pigment present in *Pseudomonas*-infected eggs, the fluorimetric estimation of which is fairly simple, although the simultaneous occurrence of riboflavin calls for the use of blanks. The particular fluorescent pigments encountered can help us to identify the type of microbial contamination present, and their concentration can provide an index of bacterial counts in contaminated samples.

## Food Additives

Many food additives can be determined fluorimetrically, although few are actually assayed routinely using this technique. One of the best examples in this context is the determination of quinine in tonic water and lemonade based on the measurement of its intrinsic fluorescence in sulfuric acid. Although the simultaneous determination of food additives usually involves a chromatographic separation, an alternative method for the determination of two antioxidants, propyl gallate (PG) and butylated hydroxyanisole (BHA), in various food samples has been described using a T-format luminescence

spectrometer and kinetic methodology. Two independent reactions have been used: the formation of the complex terbium(III)–PG and the reaction of BHA with the oxidized form of Nile Blue. The absence of overlap in the emission spectra of the two systems has made it possible to measure the additives separately in each channel of the instrument, avoiding the use of a chromatographic separation.

Gelling agents based on polysaccharides are important food additives, especially used in freeze-dried products to control the consistency of the reconstituted food. CE has been utilized to investigate the monosaccharide composition of hydrolyzed gelling agents in food samples, using 2-aminoanthracene as the derivative reagent. CE has also been applied to the separation of carrageenans, which has been derivatized with 9-aminopyrene-1,4,6-trisulfonic acid and detected using LIF.

### Fluorescence Spectroscopy in Adulteration and Quality Control of Foods

The high sensitivity and simplicity of fluorescence spectroscopy justify the common use of this technique in these fields. It has been widely applied to characterizing citric juices and investigating their alteration, such as the adulteration of lemon oil with grapefruit oil. While grapefruit oil contains an ether of umbelliferone, which is released on acid hydrolysis, lemon oil contains other nonfluorescent hydroxycoumarins. The adulteration of saffron, which is relatively frequent because of its high price, can be detected using TLC with fluorimetric detection. Saffron can be differentiated from some substitutes because it is not fluorescent under UV radiation.

Although edible oils and fats are usually assayed using GC, spectrofluorimetry has been used for straightforward screening of their quality. Thus, vegetable oils exhibit a characteristic fluorescence due to the presence of carotenoids, chlorophyll, and PAH residues. Numerous methods have been developed to distinguish olive oils of different quality. Also, the presence of glycerin, which is an indication of rancidity since it is released during enzymatic breakdown of fat, can be detected fluorimetrically by condensation with  $\beta$ -naphthol, 2,7-dihydroxynaphthalene, and anthrone.

Fluorescence spectroscopy has been used routinely to detect decay and spoilage in foods, the occurrence of which is occasionally signaled by the appearance of fluorescence. Thus, orange rot appears as light

fluorescence on a dark background of the fruit. Other fruits possess a characteristic fluorescence that is either altered or removed by spoilage. Fresh milk and cream emit greenish-yellow fluorescence that is mainly due to riboflavin and changes to blue fluorescence, typical of lumichrome, on exposure to daylight for long periods of time or on irradiation by other means. Detection of the production of biogenic amines, such as cadaverine and agmatine, in fish using LC and postcolumn derivatization with OPA has been proposed as a freshness indicator of the stored fish. An example of the application of FIAs in food quality control is the determination of skatole, a compound causing boar-taint in pig back fat samples. The method has been developed in a homogeneous format and is based on the use of europium(III) as a label together with kinetic methodology.

## Introduction

Foam fractionation and flotation are the terms given to the separation processes by which inorganic and organic ions, molecules, colloidal particles, and suspended solids are floated from aqueous solutions with a rising stream of bubbles. Flotation is sometimes used to mean the removal of particulate materials by bubbling, whereas foam fractionation indicates the foaming off of dissolved materials by adsorption on bubble surfaces. Overlap and inconsistency in terminology are often encountered.

In general, the substance to be floated should be hydrophobic. When the substance is hydrophilic, surfactants are added to render it (or its surface) hydrophobic before flotation.

The best-known bubble separation technique is probably ore flotation, which is used for the recovery of valuable minerals from suspensions of crushed ores. For example, sulfide particles are selectively rendered hydrophobic with xanthate ions and floated by bubbling, leaving oxides and silicates in the solution. Another well-known application is the separation of surface-active materials such as surfactants and proteins by simple bubbling.

In 1959, Sebba proposed the technique of ion flotation, in which the desired metal ions or their complexes were allowed to react with surfactant ions and the compounds were floated by bubbling. Selective separation was achieved by using appropriate surfactants and complexing agents, and by adjusting their concentrations and flotation pHs. The first analytical application was reported by Tomlinson and Sebba. An excess of cationic dyestuff (crystal violet) was added to a solution containing milligram quantities of oleate ions, and the resulting reaction product was floated with bubbles. The oleate ions in the original solution were determined by measuring the decrease of absorbance of the dye in the solution. In 1968, Mizuike *et al.* tried to apply the bubble separation technique to the separation and preconcentration of trace heavy metals from matrix elements.

Flotation mechanisms and experimental conditions have since been studied in detail, and the flotation apparatus has been greatly improved. Today, the bubble separation technique is an

indispensable method, especially for the separation and preconcentration of trace constituents in environmental, industrial, and biological samples.

## Principles

Bubble separation techniques can be grouped into three classes: precipitate flotation, colloid flotation, and ion flotation (involving foam fractionation). Precipitate flotation is the most powerful of these separation techniques and is popular in the field of analytical science. Therefore, the principles and important experimental factors in bubble separation techniques are explained with reference to precipitate flotation.

### Precipitate Flotation

Figure 1 is a schematic representation of precipitate flotation with small bubbles and surfactant ions having opposite charge to the precipitate surface. The hydrophilic groups of surfactant ions are oriented toward the surface of the precipitate, and hence the precipitate is made effectively hydrophobic. Small bubbles are easily trapped on the surface of the precipitate and flotation is achieved. An excess of surfactant serves to form a stable foam layer that prevents the redispersion of the floated precipitate into the bulk solution (see Figure 2).

The flotation behavior of hydrated iron(III) oxide is shown in Figure 3. The charge of the precipitate surface changes from positive to negative with increasing pH of the solution. Therefore, flotation is achieved with sodium oleate (anionic surfactant) up to the isoelectric pH, and with benzalkonium chloride (cationic surfactant) at higher pHs. In the absence of ethanol, flotation recovery is not complete because large bubbles (1–1.5 mm in diameter) ascend rapidly and disperse the floated precipitate. By adding small amounts (~1% v/v) of ethanol, however, numerous tiny bubbles (0.1–0.5 mm in diameter) are generated and successful flotation (complete flotation followed by formation of a stable foam layer) is achieved. Both anionic and cationic surfactants are useful for flotation around the isoelectric pH, because tiny bubbles are easily trapped in the interstitial spaces of the flocculent hydrated iron(III) oxide precipitate. Ethanol, which is often used as solvent for a surfactant, prevents the coalescence of bubbles appearing from adjacent pores of the sintered-glass disk (porosity 4) at the bottom of a flotation cell.

**Figure 1** Flotation of precipitate.

**Figure 2** Before and after flotation of precipitate.

Similar results are obtained with other water-miscible organic solvents (e.g., methanol, acetone, and methyl cellosolve).

The combined use of two kinds of surfactants is sometimes recommended. Sodium oleate plus sodium dodecyl sulfate (SDS) is one of the best combinations for flotation from seawater samples. Sodium oleate functions in the flotation of the precipitate and

**Figure 3** Flotation of iron(III) hydroxide in the presence (○, Δ) or absence (●, ▲) of ethanol.

SDS in the formation of a stable supporting foam layer. With only sodium oleate, a stable foam layer is not formed on the solution surface, probably due to the reaction of an excess of sodium oleate with magnesium ions in seawater. With only SDS, most of the precipitate does not float.

The following precipitates are successfully floated from aqueous solutions with suitable surfactants and ethanol:  $\text{Mg}(\text{OH})_2$ ,  $\text{Al}(\text{OH})_3$ ,  $\text{Ti}(\text{OH})_4$ ,  $\text{Cr}(\text{OH})_3$ ,  $\text{Fe}(\text{OH})_3$ ,  $\text{Fe}(\text{OH})_2$ ,  $\text{Co}(\text{OH})_2$ ,  $\text{Ni}(\text{OH})_2$ ,  $\text{Cu}(\text{OH})_2$ ,  $\text{Zn}(\text{OH})_2$ ,  $\text{Zr}(\text{OH})_4$ ,  $\text{In}(\text{OH})_3$ ,  $\text{Sn}(\text{OH})_4$ ,  $\text{Sb}(\text{OH})_3$ ,  $\text{Bi}(\text{OH})_3$ ,  $\text{Th}(\text{OH})_4$ ,  $\text{CdS}$ , and  $\text{PbS}$ .

Flotation without a surfactant is possible in the separation of organic precipitates. A water-insoluble organic precipitant is first dissolved in a

water-miscible organic solvent, and then the organic solution is added to an aqueous sample solution. After stirring for several minutes, flocculent precipitates are formed; these are nearly completely floated by bubbling because tiny bubbles are easily trapped in their interstitial spaces. The resulting precipitate layer is relatively stable. Flotation with surfactants is, of course, possible. However, after the collection of precipitates, the foam mixed with the precipitates cannot be destroyed by adding organic solvents (e.g., ethanol and diethyl ether), because the solvents also dissolve the precipitates. The following organic precipitates are successfully floated without any surfactant: *p*-dimethylaminobenzylidenerhodamine, dithizone, thionalide, 2-mercaptobenzothiazole, 2-mercaptobenzimidazole,  $\alpha$ -benzoin oxime, and 1-nitroso-2-naphthol.

Precipitate flotation is more rapid and convenient than conventional filtration and centrifugation. Furthermore, precipitate flotation needs less experimental skill and is more reliable and rapid, compared with colloid and ion flotation.

### Colloid Flotation

Colloidal particles are floated by adding surfactant ions of opposite charge to the colloids. During flotation, a scum is generally formed on the solution surface, which is then supported by a stable foam layer. Compared with precipitate flotation, the flotation efficiency is greatly affected by the experimental conditions (e.g., pH, quantity of surfactants, and bubbling time). Therefore, colloidal particles are sometimes coagulated to form bulky precipitates and then floated rapidly. For example, sulfate ions are useful to coagulate hydrated iron(III) oxide colloids at pH 4–5.

### Ion Flotation

Ion flotation originally meant the process by which surface-inactive ions are floated with surfactants of opposite charge to the ions to form a scum on the solution surface. This concept has been extended to include foam fractionation, where dissolved substances (e.g., ions, organic and inorganic molecules) are floated by adsorption on bubble surfaces and copious foam is generated on the solution surface.

The optimum operating conditions for ion flotation vary widely from system to system. The flotation pH, bubbling time, and gas flow rate should be carefully optimized, because in most cases it is difficult to observe when the flotation is complete. The quantities of surfactants should be greater than the stoichiometric amounts, but large excesses may decrease the flotation efficiency. An increase in the quantity of

coexisting ions generally decreases the flotation recovery, probably due to competition between the desired ions and coexisting ions for surfactants.

Ion flotation, in which the desired ions are floated and immediately collected in a water-immiscible organic solvent placed over the sample solution, is also useful. This method is often called solvent sublation.

## Instrumentation

Figure 4 shows typical flotation cells for batchwise and continuous-flow operations. Flotation cells are easily prepared by inserting a bubbler into a graduated cylinder or by connecting a long glass tube to a glass filter (porosity 4 commonly used, nominal pore size 5–10  $\mu\text{m}$ ). A rising stream of tiny bubbles is produced by passing nitrogen or air through the sintered-glass disk. A magnetic stirrer is used to ensure that the bubbles are attached to the precipitate that forms under the bubbler. For continuous-flow operation, the dimensions of the flotation cell should be carefully optimized. When the diameter of the cell is reduced, the sample stream disturbs the flotation. The height of the sample inlet should be determined in order that both redispersion of floated substances and loss through a drain do not occur. Electrolysis can be used for the flotation, where tiny bubbles of oxygen and hydrogen are produced at the anode and cathode installed in a flotation cell.

Some useful techniques for the collection of flotation products (precipitate, scum, and foam) are shown in Figure 5. A sampling bottle, spatula, and pipette are useful for direct collection. A detachable polyethylene insert is helpful for the complete recovery of flotation products, which often adhere strongly to the inner wall of the flotation cell. Suction through the sintered-glass disk is also convenient for the separation of precipitate and scum from the mother liquor. Copious foams are ruptured by contact with small amounts of organic solvents (e.g., ethanol, 1-butanol, and diethyl ether).

## Applications

Precipitate flotation has mainly been used for the separation of collector precipitates for trace analysis. Trace elements at the low microgram per milliliter level or less are nearly completely coprecipitated with small amounts of inorganic or organic collector precipitates, which are then floated by bubbling with or without the aid of surfactant ions. This method is

**Figure 4** Typical flotation cells.

**Figure 5** Collection of precipitate, scum, and foam.

often called coprecipitation flotation. Some typical examples are described below.

### **Simultaneous Preconcentration of Heavy Metals in Natural Water**

Trace heavy metals in 1 l of sample can be coprecipitated with indium hydroxide at pH 9–9.5 by using 1 ml of indium nitrate solution ( $100 \text{ mg In ml}^{-1}$ ) and  $0.3 \text{ mol l}^{-1}$  sodium hydroxide solution. After adding 2 ml of sodium oleate solution ( $1 \text{ mg ml}^{-1}$  in 70% ethanol) and 1 ml of SDS solution ( $4 \text{ mg ml}^{-1}$  in 70% ethanol), the precipitate is floated with tiny bubbles and collected in a sampling bottle. The precipitate is dissolved in 2 ml of  $14 \text{ mol l}^{-1}$  nitric acid and 3 ml of water, and analyzed by inductively coupled plasma atomic emission spectrometry for chromium(III), manganese(II), cobalt(II), nickel, copper(II), cadmium, and lead.

### **Preconcentration of Silver in Seawater**

Traces of silver can be concentrated by adding 50 ml of 2-mercaptobenzothiazole solution ( $40 \text{ mg ml}^{-1}$  in acetone, purified by the amalgamation method) to 3 l of sample (acidified to pH 1). By stirring the solution, the precipitate is coagulated and then floated to the solution surface. After the suction of the mother liquor through the sintered-glass disk, the precipitate is destroyed with  $14 \text{ mol l}^{-1}$  nitric acid and 30% hydrogen peroxide. The resulting residue is dissolved in 5 ml of  $8 \text{ mol l}^{-1}$  nitric acid and analyzed by atomic absorption spectrometry for silver.

### **Radiochemical Separation of Cobalt-60 in Seawater**

To a 100 l sample, 500 ml of  $12 \text{ mol l}^{-1}$  hydrochloric acid, 10 ml of cobalt carrier solution ( $1 \text{ mg Co ml}^{-1}$ ), and 400 ml of 1-nitroso-2-naphthol solution ( $5 \text{ mg ml}^{-1}$  in ethanol) are added. With peristaltic pumps, the sample solution,  $1 \text{ mol l}^{-1}$  aqueous ammonia, and anionic surfactant solution ( $0.8 \text{ mg ml}^{-1}$  in 70% ethanol, sodium oleate–SDS = 1:3) are fed into a 1 l reaction bottle at flow rates of 500, 35, and  $10 \text{ ml min}^{-1}$ , respectively. In the reaction bottle, the cobalt chelate is captured by a flocculent precipitate of indium hydroxide at pH 8.5–9. The contents of the bottle are continuously transferred to a flotation cell and flotation continues until the completion of sample feeding. The precipitate is sucked into a sampling bottle and then dissolved in 100 ml of  $6 \text{ mol l}^{-1}$  hydrochloric acid. The cobalt chelate is separated from indium ions by extraction with chloroform and destroyed by dry oxidation. After dissolving the residue in 5 ml of  $8 \text{ mol l}^{-1}$  hydrochloric

acid, the cobalt is extracted into 5 ml of tri-*n*-octylamine ( $50 \text{ mg ml}^{-1}$  in xylene) and the  $\beta$ -activity of cobalt-60 is counted with a liquid scintillation counter.

Some examples of applications of precipitate flotation, using both inorganic and organic collector precipitates, are summarized in Tables 1 and 2. Organic collector precipitates are generally much more selective in the separation of metal ions than inorganic collector precipitates.

Based on the principles of precipitate flotation, a rapid and convenient separation technique has been developed for the determination of toxic heavy metals adsorbed on suspended solids in freshwater. Because suspended solids are negatively charged species, they are rendered hydrophobic and coagulate to form bulky flocs with a cationic surfactant and sodium chloride (to increase the ionic strength). The flocs are easily floated by bubbling and are then treated in nitric acid to determine the desorbed heavy metals (e.g., chromium, manganese, copper, cadmium, and lead) by graphite furnace atomic absorption spectrometry.

Colloid flotation can also be used for separation and preconcentration in trace analysis, by adsorbing trace elements on colloidal particles. This method is known as adsorbing colloid flotation. In most cases, however, the collectors used are visible precipitates (not colloidal particles). Therefore, these examples should properly be included in precipitate flotation.

Ion flotation has the advantage that the desired ions are separated without collector precipitates. Three typical examples of ion flotation are described below.

### **Preconcentration of Uranium(VI) in Seawater**

To a sample of 500 ml, 50 ml of arsenazo-III solution ( $1 \text{ mg ml}^{-1}$ ) and 50 ml of  $1 \text{ mol l}^{-1}$  acetate buffer solution (pH 3.5) are added. The resulting uranium(VI)–arsenazo-III anion complex is floated with 4 ml of tetradecyldimethylbenzylammonium chloride solution ( $10 \text{ mg ml}^{-1}$ ) and a scum is formed on the solution surface. After the suction of the mother liquor through the sintered-glass disk, the scum is ignited and then dissolved in 5 ml of  $9 \text{ mol l}^{-1}$  hydrochloric acid for the spectrophotometric determination of uranium.

### **Preconcentration of Heavy Metals in Hot Spring Water**

To a sample of 1 l, 2 ml of  $9 \text{ mol l}^{-1}$  sulfuric acid, 5 ml of hydroxylammonium sulfate solution ( $100 \text{ mg ml}^{-1}$ ), and 3 ml of  $0.01 \text{ mol l}^{-1}$  1,10-phenanthroline solution are added. The pH of the solution is adjusted to 4 with  $6 \text{ mol l}^{-1}$  aqueous

### Preconcentration of Anionic Surfactant Ions in Freshwater

To a sample of 200 ml, acetate buffer solution (pH 5) and 0.5 ml of ethyl violet solution (1 mg ml<sup>-1</sup>) are added. The resulting ion pairs of anionic surfactants are floated by bubbling and captured in 5 ml of organic solvent (toluene–methyl isobutyl ketone = 9:1). The organic phase is analyzed by spectrophotometry for anionic surfactants (mainly SDS).

Some examples of the application of ion flotation are summarized in **Table 3**. The recovery of valuable proteins and pharmaceutically important compounds by using foam fractionation and ion flotation is becoming increasingly important because of their economical and simple procedures.

## Introduction

The science of food and nutritional analysis has developed rapidly in recent years. Food scientists analyze foods to obtain information about their composition, appearance, texture, flavor, shelf life, etc., and also to guarantee the quality of the product. Nevertheless, the term food and nutritional analysis is often thought only to be concerned with the determination of food composition and its nutritive value/quality.

The analysis of food began in the nineteenth century utilizing microscopy. It was the first analytical technique used by analysts such as Accum and Hassall to identify food components and to detect adulteration. The development of improved analytical methods to determine the composition of foods (such as Kjeldahl method

for nitrogen estimation in 1885), together with the concern over adulteration resulted in the introduction of statutory legislation over the composition of important food products in many countries. These forms of controls continued for ~100 years until the 1970s, when rapid advances in food science and technology revolutionized the manufacture of food. Media attentions have also brought a public awareness of the links and causation between diet and health. As a result, today's sophisticated consumers have become more concerned over the quality and compositions of their food purchases, the contained ingredients, and the presence of additives and contaminants. Therefore, knowledge of the chemical and biochemical composition of foods is important to the health, well-being, and safety of the consumers. Analytical characterization is also important for compliance with legal standards, quality assurance, and determination of nutritional value.

Various types of modern food analytical techniques have been developed, including electrophoresis, chromatography, spectroscopy, rheological techniques, and sensory evaluation, to meet the challenge of providing information on the diverse components of these complex food materials.

## Information Sources

### Standard Official Methods and Modern Information Retrieval Systems

Standard analytical methods approved by professional associations/scientific agencies such as Association of Official Analytical Chemists, The American Association of Cereal Chemists, and American Oil Chemist Society are used in food industry. (These methods are being improved and updated from time to time.) The computerized systems for storing and retrieving scientific information are now well developed (Table 1).

### Sampling

Food is a heterogeneous mixture of chemical substances; therefore, its analysis requires adequate methods of sampling and preserving. The analytical

method selected must be specific, accurate, precise, and sensitive for the substance to be analyzed. The sampling includes sample selection, preparation, and labeling. If it is not carried out properly/correctly it leads to variability of results. Ideally, the sample analyzed should have exactly the same properties as the bulk of the sample (population) from which it was taken. The major steps in sampling are identification of the population from which the sample is to be taken, location from which the sample should be collected, and method of obtaining the gross samples.

## Techniques and Methods

### Spectroscopic Techniques

A variety of spectroscopic techniques has been developed to analyze food materials (Table 2).

### Rheological Techniques

Rheology is the study of flow of matter and deformation and these techniques are based on their stress and strain relationship and show behavior intermediate between that of solids and liquids. The rheological measurements of foodstuffs can be based on either empirical or fundamental methods. In the empirical test, the properties of a material are related to a simple system such as Newtonian fluids or Hookian solids. The Warner-Bratzler technique is an empirical test for evaluating the texture of food materials. Empirical tests are easy to perform as any convenient geometry of the sample can be used. The relationship measures the way in which rheological properties (viscosity, elastic modulus) vary under a

specific system of applied forces. These techniques provide a measure of baking quality of flours, thickening properties of biopolymers, texture, hardness, flakiness, consistency in food, tenderness of meat, and texture of fruits and vegetables. Rheological techniques have now become essential tools in food science and technology.

### Biological Techniques

Biological techniques encompass two methodological approaches: live systems and biochemical techniques. Live systems employ (1) whole animal, (2) microorganisms, and (3) cell and tissue culture methods as tools in food analysis. Biochemical techniques include uses of enzymes and immunochemical techniques (Table 3).

**Live systems as analytical tools** Different life systems have been utilized in assessing composition and nutritional quality of foods.

The whole animal techniques are used in the nutritional and toxicological evaluation of foods by providing a combined assessment of digestibility, metabolism of food, and nutritional evaluation of quality of foods. These approaches are aimed at determining the changes in the nutrient content in animal body in response to feeding a diet or meal containing that nutrient. The animal used in conducting food analysis assays include albino rats and mice, and guinea pigs, chicken, ducks, hamsters, gerbils, dogs, and monkeys.

The changes in nutrient content and energy value of foods required for animal body involves the measurements on animal body itself. These assays are based on body weight changes for analysis of food protein and energy and include protein efficiency ratio (PER), net protein ratio (NPR), and multilevel assays. The second approach to estimate change in the nutrient content of the body involves measurements of intake and output of nutrients from the body and assay includes nitrogen or energy balance, net protein utilization (NPU), biological value (BV), and net energy.

The animal assay for evaluating toxic constituents (natural or added) of food uses lethality as an index and determines the dose of that toxic chemical to kill/affect 50% of the test animal, referred to as LD<sub>50</sub> dose. The response criteria can be toxicity, carcinogenicity, mutagenicity, reproduction, and metabolism.

**Microbiological food assay** Microbiological food assays involve the use of microorganisms as a substitute for a higher animal. Since some of the nutritional requirements of microorganisms and experimental animals are similar, it is possible to use microbiological food assays to determine the substances that are essential constituents of living cells. These are based on the principle that in the presence of limiting amount of specific nutrients, the amount of growth is a function of concentration of this nutrient. These are used for determination of amino acids, vitamins, nucleic acids, heavy metals, growth factors, and the nutritional value of proteins and antibodies. The microorganisms used for the assay are bacteria, fungi, algae, yeast, and protozoa. The test organism selected is based on nonpathogenicity, sensitivity, and specificity to the nutrient to be assayed, its rapid and reproducible growth, and ease in making growth measurements. It can be assayed after adding the food sample extract to a liquid medium or gel medium, inoculated with the microbial culture followed by

growth stimulation, and then by turbidimetry measurement, gravimetry measurement, diffusion plate assay, and metabolic product assay.

**Cell and tissue culture methodology** This method uses cell, tissue, or organs for analytical purposes. These have been used in food toxicology and safety. Toxic chemicals like pesticides, food additives, and chemicals produced during processing and cooking of foods are tested for their toxicity, mutagenicity, and oncogenic properties using tissue culture techniques.

**Biochemical techniques** These techniques include immunochemical and enzymatic techniques.

Immunochemical techniques are based on specific interactions of antibodies with antigens. Since macromolecules are present in microorganisms, food, and agricultural products and are good antigens, the antibodies against these molecules can be obtained in response to the immunization with antigens, the substances foreign to animals. The antibodies produced in response to a particular antigen are capable of recognizing and binding due to the complementary binding site on the antibody with that of antigen. The methods employed in food analysis include hemagglutination, precipitation, immunodiffusion, immunofluorescence, immunoelectrophoresis, radioimmunoassays, and enzyme immunoassays. Enzymatic analysis means analysis with the aid of enzymes using specific enzymatic reactions. The enzymatic techniques are highly useful because of specificity and sensitivity for measuring the concentration of compounds. This reduces the time of analysis and avoids lengthy separations of the components. The immobilized enzyme systems with electrochemical detection methods are used for analytical determinations of food components that would be laborious or otherwise impossible. These techniques require small amounts of sample and do not require components to be extracted from their matrix. Enzymatic methods are used in the determination of structure of polymeric macromolecules, quality indices of foods, and nutritional and physical induced changes in human beings.

### Sensory Evaluation

Sensory evaluation is a scientific discipline used to evoke, measure, analyze, and interpret reaction to those characteristics of food material as they are perceived by the senses of sight, smell, taste, touch, and hearing (sound). The sensory attributes of quality of food are measured to determine consumer acceptance/preference in order to manufacture an

acceptable and affective product at maximum production economy. The sensory attributes include appearance (color, size, shape, and consistency of liquid and semisolid products), kinesthetic (texture, consistency, and viscosity), and flavor (taste and odor). The evaluation is done to determine quality criteria by which raw materials and finished products may be graded and classified. The sensory techniques help food scientists to determine the conformity of a food with established government or trade standards and food grades and product development while maintaining desirable sensory characteristics. The technique of sensory evaluation uses humans as data generators; hence, it is influenced by cultural, psychological, religious, social, and climatic factors, physical and educational status of an individual, availability, and nutritional knowledge. Highly trained groups of experts are employed for evaluation to minimize the effects of such factors. For complete sensory evaluation of food, two types of tests – analytical sensory tests and affective tests (like-dislike) are performed (Table 4).

The analytical sensory tests are confined to sensitivity, discriminatory, quantitative (intensity), and descriptive or qualitative analysis of the sensory attributes of food.

A sensitivity test is a measure of sensitivity to a human stimulus and is expressed as threshold, which is a fixed value at a given moment of time. The threshold may be absolute or differential, which is measured using various psychological methods. The threshold is determined by approaching and receding from standard stimulus by short steps and the threshold is that step where the judge's response shifts from one category to another. In the method of average error (or the method of adjustment), the judge adjusts the concentration of the comparison with the

standard stimulus. The frequency method records each comparison stimulus against a standard stimulus many times, thereby creating a difference response.

### **Discrimination Tests**

Food analysis is based on difference testing, the fundamental approach to sensory analysis of food. A simple difference test permits one of the two responses 'Yes, there is a difference' or 'No, there is a no difference'. In directional difference testing, a judge is asked which sample is more in a predefined characteristic. The predesignated standard must be similarly understood and used by all the judges. A large number of difference tests, single stimulus, paired comparison, paired difference, triangle, dual standard, multiple standard, and multiple pairs, are used to detect the sensory differences (such as sweetness, softness, color, etc.) between the two or more samples.

### **Quantitative Test (Intensity)**

This approach of sensory evaluation is based on description of scaling, i.e., ranking category (or internal) and magnitude estimation (or ratio). Ranking is used for grouping of the products based on their quality or order of preference. The scoring on category scale involves the use of a limited number of categories, designated in terms of numbers, letters, or points on a line. The magnitude estimation is a type of ratio scaling that measure the relationship between physical and sensory criteria. Any number is assigned to the first stimulus. A proportional number is assigned to reflect its strength in comparison to the first.

### **Descriptive Analysis**

In descriptive analysis small groups of highly trained judges with considerable experience with the commodity under study develop adjectives to characterize the qualitative properties of the product (attributes like appearance, aroma, texture, taste, etc., are analyzed). The data of sensory analysis experiments are subjected to statistical analysis to get reliable results. Instrumental methods are also used to correlate physicochemical measurements with sensory judgments (Table 5).

**Effective testing/acceptance testing** By acceptance testing we mean measuring liking or preference for a product. Preference is that expression of appeal of one product versus another that can be measured directly by comparing two or more products with each other. The nine-point hedonic scale method

**Table 4** Human response of sensory systems corresponding to selected physical properties of foods

<i>Physical property (stimulus)</i>	<i>Sensory system</i>	<i>Human sensation</i>
Density	Kinesthetic, haptic	Heavy, light
Moisture content	Haptic, thermal	Dry, wet, soggy
pH	Gustation, pain	Harsh, sharp, sour
Radiant energy	Visual	Appearance, color
Shear	Kinesthetic, haptic	Hard
Surface abrasion	Haptic, pain	Rough, prickly
Solubility	Gustation	Taste
Temperature	Thermal system	Cold, hot
Texture	Olfaction	Odor
Vapor pressure	Kinesthetic, haptic	Thin, thick
Vibration/pitch	Auditory	Sound, e.g., crisp, crunchy, sizzle

**Table 5** Analytical methods and consumer measurements of sensory attributes

<i>Analytical tests</i>				
<i>Stimulus concentration</i>				
<i>Sensitivity</i>		<i>Quantitative</i>		<i>Qualitative</i>
<i>Threshold</i>	<i>Discrimination</i>	<i>Scaling</i>	<i>Duration</i>	<i>Descriptive analysis</i>
Methods of limits	Paired comparison	Ordering or ranking	Time intensity	Texture profile
Methods of adjustments or average error	Paired difference	Category (internal)		Flavor profile
Frequency method	Duo-trio	Magnitude estimation (ratio)		Dilution profile
	Dual standard			Quantitative descriptive analysis
	Multiple standard			Other methods
	Triangle			
<i>Consumer tests</i>				
<i>Effective</i>				
<i>Acceptance</i>	<i>Preference</i>	<i>Hedonic test</i>		
Accept/reject what is available	Select one over the other	Degree of like and dislike		

occupies a niche for the sensory evaluation of product acceptance/preference. The measure of liking preference is a sensory evaluation model for measuring product acceptance and it represents the final phase of test resources with discrimination and descriptive analysis test. The sensory acceptance test is a cost-effective resource that has a major role in the development of successful products.

The scale was developed to access the degree of acceptability of food items, beverages, cosmetics, paper products, etc., by measuring the degree/magnitude of like/dislike.

### Nutritional Evaluation of Food Processing

Although processed foods are not considered to be as nourishing as fresh and unprocessed foods, there is an increasing demand for processed foods, which are available throughout the year. Food processing involves a wide variety of industrial processes with a correspondingly large variety of products. The optimum quality maintenance of the product attributes are compared in relation to the origin as 'fresh like' characteristics of preserved fresh products and 'just cooked like' attributes of preserved cooked products. New techniques such as modified atmosphere packing, edible and biodegradable packing materials, high-pressure short-duration treatment, biopreservation, high-voltage inputs, and a combination of different mild treatments help in preserving the quality attributes of the processed food.

## Food Components

Knowledge regarding the major constituents of food (e.g., carbohydrates, amino acids, proteins, lipids, dietary fiber, and nutritional and antinutritional components) is necessary so as to gauge the extent of any structural change that occurs during processing and storage of foods, which may affect the quality and safety of the food product.

### Major Components

**Moisture** Water content/moisture content is the most ubiquitous substance in nature, the largest single constituents of all living things and affects quality, value, and freshness of food and is of major concern in food, paper, and plastic industries. Moisture determination is a widely used fundamental analytical operation, which satisfies the technological, analytical, commercial, and regulatory necessities in the processing, testing, and storage of food products and is an index of economic value, stability, and nutritional quality of food products.

Removal of water for processing/storage purposes either by conventional dehydration or freezing and drying alters the native functional properties of foods. Simple, rapid, and accurate methods for moisture determination in raw, processed, and stored food products are used to know the nutritive value of food products. A homogenous food sample should be prepared using a number of electrical/mechanical

devices like blenders, graters, grinders, homogenizers, and mincers for the determination of moisture by any of the analytical methods given in **Table 6**, which are classified as direct and indirect procedures. The weight of sample is taken before and after it is dried, and the moisture content is calculated. Instruments used for moisture determination are simple to use and provide rapid and reliable measurements and are suitable for routine quality control applications.

**Carbohydrates** Carbohydrates are a major source of energy for humans and are present in all foods (grains, vegetables, fruits, and milk), and vary in form from simple monosaccharides (fructose, glucose, galactose, sorbitol) to oligosaccharides (maltose, sucrose, lactose, raffinose, stachyose, verbascose), and more complex polysaccharides (starch, cellulose, etc.).

The complete analysis of foodstuffs may require the determination of simple sugars and reducing sugars (fructose, glucose, galactose, sorbitol, maltose, lactose), oligosaccharides (sucrose, raffinose, stachyose, verbascose), polysaccharides (starch, cellulose, etc.), and fibers, which vary in amount/form and all of which may play an important role in the quality of the product. Methods of

carbohydrate determination in foods are summarized in **Table 7**.

Neutral monosaccharides, uronic acids, hexosamines, and sialic (neurominic acids) are identified and determined by specific colorimetric reactions. The principle behind the techniques rests on the condensation of the degraded products of the neutral monosaccharides (hexose, pentose and methyl pentose) by sulfuric acid with anthrone, cysteine hydrochloride, orcinol, and phenol reagents. Uronic acids may be determined by colorimetric and manometric procedures. While sialic acids are determined after chemical/enzymatic hydrolysis, gravimetric and Van-Soest detergent based methods are used to determine cellulose, hemicellulose, and fiber.

**Amino acids and proteins** A large variety of proteins, either from animal origin (eggs, fish, meat, and milk) or plant origin (cereal, pulses, fruits, and vegetables) is available from food sources. There is a practical need to determine amino acids, proteins, and protein quality, and to monitor and regulate protein quality in food production, processing, storage, and marketing, which emphasizes the importance of protein quality. The comprehensive nutritional evaluation of protein quality of food and food products begins with the determination of nitrogen content, essential amino acid concentrations, amino acids, protein types, and assessment of

**Table 6** Classification of analytical methods for moisture determination

<i>Direct methods</i>	<i>Indirect methods</i>
Direct methods usually yield accurate and absolute value and are manual and time consuming	Indirect methods are rapid, nondestructive and easily automated
<i>Drying method</i>	<i>Physical and electrical methods</i>
Chemical desiccation	AC and DC conductivity
Freeze-drying	Dielectric capacitance
Oven drying	Microwave absorption
Vacuum drying	<i>Spectroscopic methods</i>
<i>Distillation method</i>	IR absorption
Azotropic distillation	Near-IR reflectance
<i>Chemical methods</i>	Nuclear magnetic resonance
Generation of acetylene	Neutron and $\gamma$ -ray scattering
Heat on mixing with $H_2SO_4$	Refractometry

Phenol/sulfuric acid	
Nelson-Somogyi	
Neocuproine	
Picric	

nutritional value including digestibility (*in vitro* and *in vivo* assays), and biological evaluation (PER, NPU, BV, growth parameters, etc.) by taking albino rats, guinea pigs, and human beings as experimental models. Enzymatic and microbiological tests may also evaluate nutritional quality of foods. Amino acids can be determined by colorimetric and enzymatic methods after hydrolysis of proteins in a specific medium used to diminish destruction of essential amino acids after separation by different techniques (column chromatography, thin-layer chromatography (TLC), gas chromatography (GC), high-performance liquid chromatography, etc.). The availability of all the essential amino acids in food proteins can be measured with the enzymatic ultrafiltration digest.

The determination of protein in food/food products depends on a measurement of a specific element or chemical group in the proteins, which may be carried out either directly by using chemical or physical properties. Based on nitrogen content, protein content can be estimated by Kjeldahl's method (AOAC). Ammoniacal nitrogen produced after destruction of organic matter of foods is multiplied by a coefficient of 6.25 for animal, vegetable, and pulse proteins and by 5.7 for cereals to obtain protein contents. Ammonia content can also be determined by using an ammonia-specific electrode, based on the difference in potential between a reference electrode and a measurement electrode, and with the help of Nessler's reagent. Protein content in food/food products may be determined by various chemical and physical methods as given in Table 8.

Specific protein components in food/food products can be determined by chromatography (ion-exchange chromatography, PC, TLC, GC, LC, etc.), electrophoresis, and immunology or their combination. It is also necessary to use high-resolution techniques such as reversed phase LC, ion-exchange LC, size-exclusion LC, slab electrophoresis, and capillary electrophoresis (CE).

All protein determination methods described are not absolute and demand some form of calibration. The Kjeldahl's method remains the only official method currently available for calibration purposes and maintains its position as the most frequently used technique for the determination of organic nitrogen in food products. CE and immunochemical (enzyme-linked immunosorbent assay) techniques are most suitable for rapid separation and quantification of individual food proteins and are promising for widespread use in food protein analysis due to their high sensitivity, specificity, and simplicity of operation. There are numerous methods for the evaluation of the nutritional quality of food proteins,

**Table 8** Methods of protein determination

Name of method	Principle used
<i>Chemical methods</i>	
Biuret method	Based on binding of copper(II) to a peptide bond in protein molecules at alkaline pH values (measured between 540 and 650 nm)
Lowry method	Based on reduction of Folin–Ciocalteu reagent by oxidation of tyrosine, tryptophan on polypeptide side chain (measured at 750 nm)
Dye binding	Based on the measurements of excess dye remaining in solution after removal of the precipitated protein–dye complex
<i>Physical methods</i>	
UV spectrophotometry	Based on absorption maximum at 280 nm, due to presence of a side chain of aromatic amino acids (Tyr and Try)
Fluorimetry	Based on emission of fluorescence excited at 275 or 345 nm
IR reflectance	Based on characteristics absorbance spectra at different wavelengths
Refractometry	Based on change in refractive index by the displacement of proteins
Turbidimetry	Based on change in intensity of light due to protein diffusion
<i>Immunological method</i>	Based on interaction between an antigen and its corresponding antibody

which are already listed as determination of amino acid composition and essential amino acids, and enzymatic tests, microbiological methods, and biological measures.

**Lipids** The analysis of lipids in food has three distinctive objectives: to determine (1) total lipid content, (2) the composition, and (3) the quality of lipids.

1. *Total lipid content.* There are physical and chemical procedures for oil/fat estimation. In physical procedures, lipids are not isolated and samples are used directly, and lipids are estimated by nuclear magnetic resonance (NMR) spectroscopy. In chemical procedures, lipids are extracted by refluxing the sample in suitable solvents (like petroleum ether) by using standard methods (AOAC or AOCS). Different classes of lipids such as neutral lipids (by nonpolar solvents such as petroleum ether, hexane), phospho- or glycolipids (by polar solvents such as methanol) can be extracted and used for

quantitative determination. TLC, column chromatography, HPLC are specific techniques used for separation of various classes of lipid.

2. *Composition of oil/fat.* To study the composition of oil/fat it is essential to test the purity of an oil/fat for adulteration, accidentally or voluntarily. The specific fatty acid in fat can be determined by GC by preparing methyl esters with sodium methoxide. Mass spectrometry coupled to GC (GC-MS) is the most powerful tool for identification of fatty acids separated by GC. Free fatty acids in oil (index of rancidity) can be determined by titration against standard alkali. Infrared (IR) spectroscopy, Raman spectroscopy, and ultraviolet (UV) spectroscopy (200–400 nm) are used to detect isomers (*trans* and *cis*) of unsaturated fatty acids and conjugated double bonds. It is important to study saponification value (depict fatty acid chain length), iodine value (give the degree of unsaturation), and hydroxyl value (free fatty acids present in fats).

### Ash and Mineral Components

The determination of ash/minerals in food contributes to assessment of a food's nutritional value and refers to elements and verifying if the food contains some minerals in quantities dangerous to the health of the consumer, whether their presence is natural or adulteration of certain food stuffs/processed or stored food products.

Ash content is a measure of total minerals and is a reliable index of nutritional value for many foods (tea, flour, edible gelatin, etc.) and feed (for poultry and cattle) and is recognized as a useful tool in determining the nature and distribution of mineral constituents of food. Ash is the inorganic material left after complete oxidation of organic material at high temperatures (500–600°C).

Ash is prepared by two direct procedures (dry and wet ashing) and an indirect technique (conductometric method that can determine the total electrolyte content of foods), governed by the following purpose: the particular constituents to be determined and the method of analysis to be used. Dry ashing is the standard method to determine ash content of a sample (AOAC). For wet ashing the sample is digested in a mixture of HNO<sub>3</sub> and HClO<sub>4</sub> (ratio 4:1).

Gravimetry (for sulfur), titrimetric (chloride), fluorimetry (Se, Al, F), colorimetric methods, or atomic spectroscopy are the traditional classical chemical methods for the determination of individual elements. Atomic spectroscopy techniques have a much higher sensitivity and specificity and provide a complete profile of elements in a food/feed. Emission

spectrometry, polarography, X-ray spectrometry, mass spectrometry, and activation analysis are important physical methods used for the determination of minerals, and are suitable for determination of alkaline metals, provide accurate and reproducible results, and offers simultaneous determination of numerous elements.

**Other food components** It is also important to analyze the toxic constituents/antinutritional factors, which are present naturally in foods, produce a deleterious effect when ingested by humans or animals. The toxic constituents/antinutritional factors, which are present naturally in foods are flatous producing factors, protease inhibitors, hemagglutinins (lectin), and saponins present in legumes, and glucosinolates (in oil seed crops), cyanogens (in bitter almond, lima beans), gossypol (in cotton), and lathyrigen (seeds of *Lathyrus* species). A large number of standard (AOAC) analytical techniques are adopted to determine the food components such as bitter compounds like anthocyanins, carotenoids (pigments), flavonoids, phenols, terpenoids, vitamins, aroma compounds, alcohols, organic acids, antioxidants and preservatives etc.

### Sample Preparation

In many respects, the sampling and preparation of a sample are critical steps in any technique of food analysis. The objective of sampling is to ensure that the sample taken for analysis is representative of a defined whole, and the method of sampling depends on the size and nature of the defined whole.

Obtaining a sample for analysis that is representative of the whole is referred to as sampling, and the total quantity from which a sample is obtained is called the population. An accurate and precise estimate of the quality of a population will only be achieved by using an adequate sampling technique because only a portion of the population is used for analysis. With a proper sampling technique, the estimated value will reflect the characteristics of the population.

Special care, however, is required in the sampling and sample preparation for food analysis because of the peculiarities of food. Foods are derived from biological substances and contain various organic compounds. Many of these components are influenced by various external and internal influences such as temperature, light, moisture, microorganisms, metabolism, and ripening. Therefore, rapid preparation of food samples enough to prevent composition change is very important in food analysis. Preparation at low temperatures during processing or storage in the frozen state is also effective for preventing the composition change of food samples.

In food analysis, analyses are generally performed on the edible portion of the defined food, discarding the nonedible portion, unless the compositions with respect to the total sample weight are required. Variations in moisture of food are relatively large, even among the same kinds of food. Therefore, values

corrected on the basis of dry matter (values of anhydrous material) or values of moisture contents are used in evaluating the analyzed value.

The general steps for sample preparation and sample processing are (1) sampling and size reduction, (2) comminution and homogenization, (3) pretreatments of the sample, such as predrying or defatting, (4) preservation of the prepared sample, and (5) cleanup of the analytical sample for instrumental analysis. This article covers the practical considerations of sample preparation necessary for food analysis.

### Sampling and Size Reduction

It is important to define clearly the population that is to be sampled. Populations are generally finite, such as the size of a defined lot, except for evaluating a process. The sampling methods selected depend on the purpose of the inspection, the nature of the product, the nature of the test method, and the nature of the population being investigated. The basic principle for sampling is probability sampling. This sampling plan provides a statistically sound basis for obtaining representative samples while eliminating human bias and, therefore, is the most desirable. The most useful sampling method is random sampling in which samples are simply taken at random from the whole population. The random sampling process allows all parts of the population to have the same chance of being sampled. The goal of providing the same chance can be achieved by means of random number tables or computer-generated random numbers. Sample size is determined by lot size, the degree of accuracy required, and the expense of the test method. However, a general standard for the number to be sampled is proposed. For instance, to select the sample flour from sacks, the number of sacks to be sampled is determined by the square root of the number of sacks in the lot.

If the mass of the collected samples is too large for analysis, it is subjected to size reduction to obtain a smaller quantity for analysis. For granular or powdered material, such as cereals, pulses, nuts, and

This article covers the practical considerations of sample preparation necessary for food analysis.

### Sampling and Size Reduction

It is important to define clearly the population that is to be sampled. Populations are generally finite, such as the size of a defined lot, except for evaluating a process. The sampling methods selected depend on the purpose of the inspection, the nature of the product, the nature of the test method, and the nature of the population being investigated. The basic principle for sampling is probability sampling. This sampling plan provides a statistically sound basis for obtaining representative samples while eliminating human bias and, therefore, is the most desirable. The most useful sampling method is random sampling in which samples are simply taken at random from the whole population. The random sampling process allows all parts of the population to have the same chance of being sampled. The goal of providing the same chance can be achieved by means of random number tables or computer-generated random numbers. Sample size is determined by lot size, the degree of accuracy required, and the expense of the test method. However, a general standard for the number to be sampled is proposed. For instance, to select the sample flour from sacks, the number of sacks to be sampled is determined by the square root of the number of sacks in the lot.

If the mass of the collected samples is too large for analysis, it is subjected to size reduction to obtain a smaller quantity for analysis. For granular or powdered material, such as cereals, pulses, nuts, and

**Figure 1** Method for size reduction (granular or powdered material).

seeds, the sample can be spread on a clean surface and divided into quarters. The two opposite quarters are combined as shown in **Figure 1**. If the mass is still too large for analysis, the process is repeated until an appropriate amount is obtained. Sample dividers that mechanically mix and divide powdered or granular materials may also be useful for the size reduction. Rotary tube dividers shown in **Figure 2** or equivalents are generally used for this purpose. For a large-sized fish, such as salmon, yellowtail, or bonito, the whole body is filleted, and the fillet from one side is sliced into pieces of equal width, and every third slice is selected, as shown in **Figure 3**. For fruits such as apples, oranges, or pears, the whole fruit is cut as shown in **Figure 4**, and pieces a, b, c, and d are selected. For liquid or viscous materials, such as milk, sugar syrup, or honey, the material should be mixed thoroughly immediately before sampling. Small quantities of liquefied materials can be mixed by rotating and shaking in a closed container that has a volume at least twice that of the sample. This kind of sampling for apparently homogeneous materials is simple, as a sample can be taken from any location, and the analytical data obtained will be representative of the whole.

**Figure 2** A rotating tube divider for reducing a large sample of dry, free flowing material to a laboratory size sample.

## Comminution and Homogenization

In order to prevent differences between samples each portion, should be ground. For the determination of moisture, total protein, and mineral concentrations, dry foods are generally ground to pass through a 0.75 mm sieve screen. For assays involving extraction (lipids, carbohydrates, various forms of protein), samples are ground to pass through a 0.40 mm sieve screen. Generally, foods grind better after predrying to the moisture level of air-dried materials. If the materials are rich in fat, defatting is recommended before grinding to avoid losses of fat as described in the section 'Defatting'.

### Grinding

Mechanical methods range from the simple mortar and pestle to power-driven hammer mills. The usable grinding devices among them are roller mills, food processors, coffee mills, and ultracentrifugal mills. Hammer mills wear well, and reliably and effectively grind cereals and dry foods. An ultracentrifugal mill grinds by beating, impacting, and shearing. The food is fed to a grinding chamber from an inlet and is reduced in size by a rotor. The small ground particles

**Figure 3** Method for size reduction (large-sized fish).

**Figure 4** Method for size reduction (fruits).

are delivered by centrifugal force into a collection pan. For small samples, especially if fine grinding is required, a ball mill is used. A ball mill grinds by rotating the material in a container half-filled with ceramic balls, which exert an impact grinding action. A chilled ball mill can be used to grind frozen foods without predrying. Grinding foods while frozen reduces undesirable chemical changes (i.e., the Maillard reaction) that can occur during milling.

The grinding process should not heat the sample, and therefore the grinder should not be overloaded to prevent the heat produced through friction. Contamination by metals from the abrasives of the mill should be avoided if trace metal analysis is to be performed. In such cases, the working parts of the grinder should be made of an inert material (glass, ceramic, or agate). After grinding the sample, all the powder ground should be collected using a clean brush.

### Homogenization

For the disintegration of moist material such as tissues, tubers, vegetables, fruits, roots, or meats, various fine-slicing devices are available. The common devices are mortars and pestles, meat mincers or grinders, mixers or blenders, bowl cutters, and tissue grinders. Bowl cutters can be used for leafy vegetables and fleshy tubers, while meat mincers may be better suited for fruit, roots, and meat. Power-driven mortars and pestles can finely subdivide and are used for making fish meat paste. Tissue grinders (**Figure 5**) are used for small samples of soft materials. Waring blenders are effective in grinding soft and flexible foods and suspensions. Knives rotating at up to 25 000 rpm disintegrate a sample into a suspension. Blenders are routinely used for the disintegration of almost all moist food samples (**Figure 6**).

**Figure 5** A tissue grinder (homogenizer with piston-type, ground glass pestle).

**Figure 6** A blender-disintegrator apparatus equipped with stainless cutting blades.

## Pretreatment of Sample

Foods rich in fat or moisture are difficult to grind or disintegrate in their intact state. Predrying and defatting are often used as a pretreatment, except for the determination of heat-sensitive and easily oxidated components such as vitamins.

### Predrying

If the components of a low-moisture, high-fat sample to be analyzed are heat-stable, predrying is recommended to the moisture level of air-dried material before grinding. For instance, an appropriate amount of the sample is cut (or loosened) into pieces and weighed. The material is placed in a porcelain dish, heated on a warm water bath (or in an electric dryer at 60–80°C), and dried. The dried material is kept for 24 h at room temperature to equilibrate it to the humidity of the environmental air. The equilibrated material is weighed and then ground.

### Defatting

When nuts and seeds, such as walnuts or sesame seeds, and processed foods containing a high level of

fat are ground, the fat oozes out and clings to the surface of the grinder, and this consequently leads to a loss of fat. Therefore, defatting is required for samples rich in fat before grinding. In brief, the weighed material is roughly ground and dried. The material is placed in a flask containing diethyl ether and kept overnight. The content of the flask is filtered, and the solid material on the filter paper is air-dried. After a thorough evaporation of the ether, the solid material is dried at 60–80°C. The dried solid material is equilibrated with air and weighed. The fat in the filtrate (ether phase) should be measured separately. Defatting is suitable for fat-rich foods. However, it should be avoided when fat-soluble vitamins are to be analyzed.

## Preparation for Specified Components

A general procedure cannot always be applied for a particular component such as dietary fiber and vitamins. Special attention should be paid to these components; a sample should be ground as finely as possible for dietary fiber analysis, and light and oxidation should be avoided for vitamin analyses.

### Dietary Fiber

Estimates of fiber are most consistent when the samples contain little fat (less than 5–10% fat), are dry, and finely ground. If the sample contains more than 10% fat, fat should be extracted by mixing the sample with 25 parts (vol/wt) of petroleum ether or hexane. After centrifugation and decantation of the organic solvent, the lipid extraction is repeated two more times. Then the sample is dried overnight in a vacuum oven at 70°C and ground finely enough to pass through a 0.3–0.5 mm mesh screen. It should be noted that loss of weight due to fat and moisture removal must be recorded and appropriate correction to the final percentage dietary fiber value found in the analysis must be made.

Nonsolid samples containing less than 10% fiber are best analyzed after lyophilization and treated as described above. Nonsolid samples containing greater than or equal to 10% fiber can be analyzed without drying if the sample is homogeneous and low in fat and if particle size is sufficiently small to allow the efficient removal of digestible carbohydrate and protein.

### Vitamins

Because some vitamins are adversely affected by conditions such as light, oxygen, pH, and heat, proper precautions need to be taken to prevent any deterioration throughout the analytical process,

regardless of the type of assay used. Most vitamin assays involve the extraction of the vitamin from its biological matrix prior to analysis. This generally includes one or more of the following treatments: heat, acid, alkali, solvent, and enzyme.

In general, extraction procedures are specific for each vitamin and designed to stabilize the vitamin. In some cases, certain procedures are applicable to the combined extraction of more than one vitamin, e.g., for thiamine and riboflavin and some of the fat-soluble vitamins. Typical extraction procedures are as follows:

- Ascorbic acid: Cold extraction with metaphosphoric acid/acetic acid.
- Vitamins B<sub>1</sub> and B<sub>2</sub>: Boiling or autoclaving in acid plus enzyme treatment.
- Niacin: Autoclaving in acid (nongrain products) or alkali (grain products).
- Vitamins A, E, or D: Organic solvent extraction, saponification, and reextraction with organic solvents. Antioxidants are routinely added to these unstable vitamins to protect them from oxidation.

Analysis of fat-soluble vitamins may require saponification, generally either overnight at room temperature or by refluxing at 70°C. In the latter case, an air-cooled reflux vessel provides an excellent control of conditions conducive to oxidation.

## Preservation of Prepared Sample

Prepared samples should be analyzed immediately. If immediate analysis is not possible, samples should be chilled or dried, depending on the storage period and conditions, the analyte, and the analyses that are to be performed. The following factors should be controlled during storage: (1) moisture changes, (2) oxidation, (3) light decomposition, (4) enzymatic changes, (5) heat denaturation, and (6) microbial changes and contamination.

To minimize oxidative changes, preservation at low temperatures under nitrogen is recommended for most foods. Compositional changes (desiccation or moisture absorption, volatilization) of relatively dry foods are reduced by storage in a closed container at ~4°C. If such containers contain powdered materials and are opened frequently to remove samples, it is advisable to check whether moisture changes have taken place. Frozen foods should be wrapped in plastic material or placed in air-tight containers to reduce dehydration.

Many food materials contain enzymes that may change the food components being analyzed. Enzyme

activity should therefore be controlled using methods that depend on the nature of the food. Heat denaturation for enzyme inactivation (e.g., use of a microwave oven) and freezer storage (–20°C to –30°C) to limit enzyme activity are common methods. However, some enzymes are more effectively controlled by changing the pH or by salting out in the sample preparation. Oxidative enzymes may be controlled by adding reducing agents.

To reduce or eliminate microbial attack, several methods can be used. They include freezing, drying, and the use of a preservative or a combination of any of the three. Commonly used preservatives include sorbic acid or sorbate, sodium benzoate, sodium salicylate, tylosin, formaldehyde, toluene, and thymol. The selection of a method or preservative will depend on the nature of the food, expected contamination, storage period and conditions, and the analyses that are to be performed.

When the prepared sample is to be used repeatedly, it is recommended that the sample be stored by dividing it into several containers in order to avoid any deterioration of the sample by repetitive freezing and thawing or exposure to air. The container should be labeled so as to identify the sample name and number, the preparation date, and the person in charge of preparation even after a long storage period.

## Novel Cleanup Techniques

Often, the crude sample extract is partially purified before the analyses. A cleanup procedure is frequently required for analyses based on various kinds of chromatography. The necessity for and the degree of cleanup required depend, to a large extent, on the instrumental detector to be used and, to a lesser extent, on the type of chromatography in the automated separation stage of the analysis. In general, the sample cleanup is the most time-consuming, labor-intensive, and error-prone step of standard analytical methods. Recently, several novel methods have been employed to decrease the time required to complete the operation and the quantities of solvents consumed in the extraction procedure.

### Solid-Phase Extraction

Solid-phase extraction (SPE) typically involves small quantities of dry 30–40 µm diameter packing material contained in a single-use polypropylene or glass cartridge (30 mg to 10 g of sorbent) or disk that can be used to purify, concentrate, or, less frequently, derivatize the analytes prior to analyses. For cartridge materials, typical retention capacities are ~5% of the sorbent mass. However, one must also account

for the other components of the crude extract that can be retained on the sorbent material. Minimum elution volumes are only 120  $\mu\text{L}$  per 100 mg of packing material. Although most packing materials are silica-based, polymeric packings can also be used. Many of the common liquid chromatography packing materials are available in one or more of the SPE formats as well. Given the limited resolving power of these systems, conventional strategies are to either selectively retain the analytes on the packing material (during the loading and rinsing cycles) or conversely retain interfering impurities while selectively eluting analytes from the packing material (elution cycle). An intermediate wash/rinse cycle can serve to separate other contaminants from the adsorbed analytes (Figure 7).

SPE has numerous advantages over traditional liquid-liquid extractions: (1) less solvent required, (2) faster, (3) less glassware needed (lower cost and potential for contamination), (4) better precision and accuracy, (5) minimal solvent evaporation for further analysis (e.g., GC), and (6) readily automated.

The most recent version of this method is called solid-phase microextraction (SPME). In this adaptation, the phase is bound onto a fine fused silica filament (*ca.* the size of a 10  $\mu\text{L}$  syringe needle). The

filament can be immersed in a sample or in the headspace above a sample. After the desired loading time, the filament is pulled into a protective metal sheath, removed from the sample, and forced through the septum of a gas chromatograph where the adsorbed volatiles are thermally desorbed from the filament. For SPME, one can readily see the advantages of simplicity and freedom from solvent usage. The primary concerns are for sensitivity limitations, precision, and the life of the filament. If the filament must be replaced because of breakage, the reproducibility of the characteristics of the old filament by the new one can be an issue.

### Gel Permeation Chromatography

Extraction processes for determining semivolatile organic compounds in food samples are not very discriminating, and the other constituents of a sample can be detrimental to the performance of the analytical method, causing deposits in the injectors of GC and GC-MS instrumentation. However, gel permeation chromatography (GPC) cleanup extracts the analyte very well from any number of other constituents.

**Figure 7** SPE based on reverse-phase chromatography. 1. Solvate the bonded phase with six to ten cartridge holdup volumes of methanol or acetonitrile. Flush the cartridge with six to ten holdup volumes of water or buffer. Do not allow the cartridge to dry out. 2. Load the sample dissolved in a strongly polar solvent. 3. Elute interfering impurities with the strongly polar solvent. 4. Elute weakly held analytes (Analyte 1) of interest with a less polar solvent. 5. Elute more tightly bound analytes (Analyte 2) with progressively more nonpolar solvents.

Various cleanup techniques can be used to remove these contaminants, but they are time-consuming, may remove target compounds, and cannot remove all interfering compounds. One of the primary classes of problem compounds is lipid in food samples. GPC cleanup is a technique that separates target compounds from a sample based on their molecular size. Since lipids are very large molecules compared to the target compounds in these methods, they are effectively removed from the extract prior to analysis. The packing gel used in GPC cleanup is porous and is characterized by the range or uniformity of that pore size. GPC operates on the principle of loading all components in an extract on the gel bed, and then selectively removing the components of larger molecular size. This procedure provides for the efficient separation of typical semivolatile and pesticide components from various higher-molecular weight compounds. This also improves method performance and extends GC column life, leading to more efficient analyses. With autosampling and automatic fraction collection as part of the GPC

system, cleanups can be performed with little or no operator intervention, requiring only that the final extracts be concentrated.

## Introduction

Foods naturally provide a series of substances that maintain the vital processes and normal development of the body, but sometimes it is desirable to add foreign substances to foods in order to modify some aspect of its properties; these substances are called food additives. The advantages of food additives are undeniable and so no country prohibits them entirely. Currently, the establishment of international positive lists and the acceptable daily intake (ADI) instituted by international organizations ensure that these additives, used at a normal dosage, will not have toxic effects on the human body. Analytical methods for the determination of additives have been developed so that the stability of these substances until the food's consumption can be monitored and also to ensure that the additives are within the limits established by legislation. The sample treatment

methods (which consume more than 70% of the analytical process) and the determinative and discriminative methodologies for the determination of additives in foods have gone through remarkable changes in the last few years as a consequence of the spectacular advances in analytical instrumentation. However, in this regard it has to be pointed out that these modern methodologies (with sophisticated instrumentation) are uncommon in many food industries.

## General Information about Food Additives

### Definition of Additive

Among the various definitions of food additives that can be found in international legislation and accords is the one adopted by the European Union (EU) in its European Community Directive 89/107/EEC of the Council of 21 December 1988: "any substance not normally consumed as a food in itself and not normally used as a characteristic ingredient of food whether or not it has nutritive value, the intentional addition of which to food for a technological purpose in the manufacture, processing, preparation,

treatment, packaging, transport or storage of such food results, or may be reasonably expected to result, in it or its by-products becoming directly or indirectly a component of such foods.” This definition emphasizes that additives are substances added intentionally to food to produce permanent functional effects and that they are generally not considered themselves to be foods.

Another food additive definition is that proposed by the Codex Alimentarius Commission: “any substance not normally consumed as a food itself and not used as a typical ingredient of the food, whether or not it has nutritive value, the intentional addition of which to food for a technological (including organoleptic) purpose in the manufacture, processing, preparation, treatment, packing, packaging, transport or holding of such food results, or may be reasonably expected to result (directly or indirectly), in it or its by-products becoming a component of or otherwise affecting the characteristics of such foods. The term does not include ‘contaminants’ or substances added to food for maintaining or improving nutritional qualities.” This definition indicates the difference between an additive that is added intentionally and a contaminant (e.g., micro-organisms and their toxins, heavy metals) whose presence in a food is unintentional.

These two examples illustrate that different food additive definitions tend to be very similar because a general consensus has been reached among the majority of countries as to what an additive is. It should also be pointed out that a special statute is normally reserved for dietetic products, nutritive substances added to food products (e.g., vitamins, amino acids, minerals, etc.), technological processing aids, and aromas.

**Classification of Food Additives**

There are many classification methods for additives: alphabetical order, numeration of each substance within a collection of chemicals, or classification by chemical function. The most common method is to group them by functional categories, that is, by anticipated use. This is the method used by the EU, which classifies additives in 24 categories, and by the Codex Alimentarius Commission, which uses 21 categories. The juxtaposition between the types of additives classified by the EU and the Codex Alimentarius Commission is not perfect, given that the number of categories is different and some categories that exist in one do not exist in the other. Furthermore, there is a large amount of multi-functional additives that could be classified in

**Table 1** Comparison between the classifications of food additives established by EU and Codex Alimentarius

<i>Improved characteristic</i>	<i>EU legislation</i>	<i>Codex Alimentarius</i>
Color	Color additives	Color additives
Color	–	Color stabilizers

Texture	Humectants	Humectants
Texture	Sequestrants	–
Texture	Enzymes	–
Texture	Bulking agents	Bulking agents
Texture	Propellants and packaging gases	Propellants

various categories. **Table 1** shows a comparison between the two different classifications.

In practical terms, a more general classification could be created that includes the additive categories previously mentioned, separating them by the functions that they fulfill in the foods:

1. additives that increase the shelf life or stability of a food,
2. additives that improve sensorial qualities without altering the nature or quality of the food in such a way that could deceive the consumer,
3. additives that improve the nutritional value of the foods, and
4. additives that aid in the manufacture, transformation, preparation, treatment, packaging, transportation, or storage of the foods.

**Food Additive Regulations**

Although additives are generally associated with the modern food industry, in reality they have been used for centuries. Preserving food has always been a

concern for humans and to achieve this end, our ancestors used salt to preserve meats and fish; preserved fruit with sugar; and pickled or canned vegetables with vinegar. During the nineteenth century and the beginning of the twentieth century, new chemical substances were discovered that could be used to preserve and color foods. In the twentieth century the need to combat commercial fraud and abuse led to the first regulation of chemical food additives by France in 1912, giving rise to the concept of a 'positive list' of chemicals allowed to be added to foods. For the first time there was explicit prohibition to the addition of chemicals or colorants, which had not been previously approved by law, to foods. The concept of positive lists of additives has lasted until today and is still in use in modern international legislation.

### **Regulations in Europe and in the United States**

Since 1988, the EU, using safety evaluations done by its Scientific Committee for Food (SCF), has harmonized the national legislation of its Member States through European Community Directive 89/107/EEC, concerning additives that can be used in products destined for human consumption. The role of the SCF has grown in importance since the adoption of directives on sweeteners (Directive 94/35/EC), colorants (Directive 94/36/EC), and other additives (Directive 95/2/EC) in 1994 and 1995. The committee, created in 1974 by the European Commission, has dedicated itself to evaluating the possible risks of food additives and elaborating guidelines for their safe use. Meanwhile, the European Commission has established concrete criteria on the purity of additives, the general or specific categories of foods with which additives may be used, and the maximum amounts that can be added to them.

In the United States, the regulation of additives is done by the Food and Drug Administration (FDA). As a response to the widespread use of many substances not approved by the FDA, in 1958 the agency created the 'GRAS lists' (Generally Recognized As Safe), comprising substances that were unanimously recognized as safe. These lists, the US equivalent to the 'positive lists' in European legislation, included only substances that had been proven by scientific practice and evidenced to be innocuous to human beings. In the same year, the 'Food Additive Amendment, to the Federal Food, Drug and Cosmetic Act (FD&C Act) was passed, requiring the explicit authorization of an additive before it could be added to a food. It also obligates the manufacturer to prove that the additive is safe in all of the forms in which it will be used. This amendment excluded two groups of substances from the additive regulation process:

those that the FDA or the United States Department of Agriculture (USDA) had deemed safe for use in foods previous to the 1958 amendment and those on the GRAS lists. In 1960, the US Congress approved the 'Color Additive Amendments' to the FD&C Act, which state that all color additives to be used in foods, cosmetics, and drugs (including externally applied drugs and cosmetics) must be approved by the FDA before being sold on the market. Since 1958, the FDA and USDA have continued to monitor all prior sanctioned and GRAS substances in response to new scientific information and evidence on the safety of these substances.

**International organizations** Every country needs to have access to reliable evaluations of the risks associated with the chemical substances used in foods, but relatively few have the technical capability and the economic means to do individual evaluations on the risks posed by the huge number of existing additives. The work done by the Joint FAO/OMS Expert Committee on Food Additives (JECFA) and the Codex Committee on Food Additives and Contaminants (CCFAC) is extremely important in this regard. Both committees were jointly created by the World Health Organization (WHO) and the Food and Agriculture Organization of the United Nations (FAO) and are dedicated to studying additives with the objective of producing international regulations for them. The JECFA works as the scientific advisor to the FAO, the WHO, the member governments of the FAO, and the WHO and the Codex Alimentarius Commission. The JECFA establishes guidelines to evaluate the safety of additives, makes toxicological evaluations, determines the ADI of each of the additives, prepares their purity specifications, and evaluates the frequency of consumption of foods that contain additives. The CCFAC advises the Codex Alimentarius Commission on food additives, contaminants, and naturally present toxic substances; examines the purity characteristics and the identity of the additives; establishes the maximum level of contaminants in foods; and advises the Products Committee of the Codex Alimentarius in which foods an additive can be used and the maximum amounts that can be added to them.

**Labeling and identification of food additives** In addition to the strict criteria applied to the evaluation of risk and the obligation of having a demonstrable use, the regulations also require that additives appear on the labels of the packaging of the foods and drinks that contain them. These labels must explain the function of the additive and its name or assigned number.

The identification of food additives using a number is an alternative to stating the specific name of the additive, which is normally quite long and has a complex chemical structure. In 1960, the EU assigned conventional numbers to food additives to better identify them. It was decided that each substance would be identified with a number (of three or four digits) preceded by the letter E. It was thought that the additives could be separated into nine categories and that each category would have 100 numbers: the first 100 numbers was assigned to color additives (100–199); the second to preservatives (200–299); the third to antioxidants (300–399); and the fourth to emulsifiers, thickeners, and gelling agents (400–499). The initial letter E indicates that the additive has been certified by the SCF as safe for use in the entire EU. In the framework of the Codex Alimentarius, in 1989 the CCFAC created the International Numbering System (INS). This numbering system was created to reach an international agreement on the identification number of additives and establish a numerically ordered list of additives that included the number of each additive and its technological function. The European Commission and that of the Codex Alimentarius have agreed to adopt the same identification numbers, although the INS system does not include the E prefix, which is reserved for the EU.

### Criteria Used to Establish the Maximum Food Additive Dose

To establish the maximum food additive dose that can be used, international authorities consider two basic criteria: technology and toxicology. On the one hand, they assess the amount of the additive that is technologically required to satisfy the objective need to include the additive in the food; on the other hand, they evaluate the innocuousness of the additive.

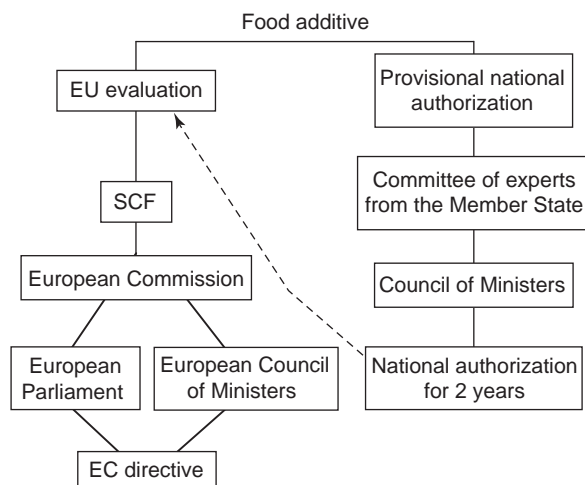

The technologically useful dose of the additive is that which accomplishes the desired effect on the food. The tests that determine the technologically useful dose must follow the guidelines established in the Good Manufacturing Practice used by the food industry.

The ADI is established by international organizations like the JECFA and the SCF after completing toxicological evaluations. The toxicological evaluation of additives is done using as reference the maximum dose that does not have a toxic effect on animals or the maximum dose that in short- and long-term toxicological studies has not had any significant toxic effects. The ADI for man is defined as the additive dose that, when consumed daily during a lifetime, does not cause a noticeable risk and is

expressed in milligrams of additive per kilogram of body weight per day.

### Legal Procedures for the Authorization of New Food Additives

The EU has established a legislative structure for the authorization of new additives proposed by either the EU or any of the individual Member States. This authorization requires a safety evaluation by the SCF, which evaluates the information provided by the manufacturers of the new food additive, including toxicity data and the function of the new additive. If the additive passes the safety standards, the committee establishes its ADI. The European Commission then develops legislation based on the committee's recommendations and then presents it to the European Council of Ministers and the European Parliament. The final result is published in a European Community Directive that obligates each Member State to make the necessary changes in their national legislation to include the new additive. Alternatively, the manufacturers can ask one of the Member States for a provisional national authorization while the EU deliberates on whether or not to legalize the additive. In this case, a committee of experts from the Member State evaluates the request, following procedures similar to those of the SCF. If the Member State establishes an ADI, the additive can be approved for use in that country for a period of 2 years, while the authorization request is studied in the EU. If the SCF authorizes the additive it is incorporated in a European Community Directive. If the SCF denies the authorization request, the additive must immediately be banned in all of the Member States. **Figure 1** summarizes the legislative procedures required to authorize additives in the EU.

**Figure 1** Legislative procedures to authorize additives in the EU.

Directive 2001/5/CE	Modification of the Directive 95/2/CE
Directive 96/77/CE	Criteria on the purity of food additives other than colors or sweeteners
Directive 98/86/CE	Modification of the Directive 96/77/CE
Directive 2000/63/CE	Modification of the Directive 96/77/CE
Directive 2001/30/CE	Modification of the Directive 96/77/CE

In the US, a request to authorize a new food additive is presented to the FDA. A petition for an additive or a colorant must include data pertaining to the toxicity of the additive accompanied by toxicological tests on animals and even on humans. To evaluate whether an additive should be approved, the agency first considers the composition and attributes of the substance, the probable amount that will be ingested, the possible long-term effects on consumers and various additional safety factors. If the additive is approved, the FDA publishes regulations that may include the types of foods in which it can be used, the maximum quantities that can be added, and how it should be identified in the food labels.

### Food Additive Legislation

European legislation is compiled in European Community Directives that are published in the Bulletin of the EU. European Community Directives affect the entire EU, setting a time limit for their integration in the legislation of each Member State, after which they are required to be enforced in the entire EU. Table 2 is a catalog of European Community Directives, updated in December 2003, that regulate positive lists of additives, standards for the purity of additives, and the maximum amounts of additives that can be added to different categories of foods.

The US additive legislation is incorporated in the Code of Federal Regulations, Title 21, Chapter 1. The content of the US legislation is organized in parts, shown in Table 3.

**Table 3** US additive legislation

<i>Part</i>	<i>Content</i>
70–82	Regulation of color additives
170–173	General regulation of food additives
174–178	Regulation of indirect food additives
180	Regulation of food additives permitted in food or in contact with food on an interim basis pending additional study
182–186	Regulation of the substances affirmed as generally recognized as safe
189	Regulation of the substances prohibited from use in human food

### Analytical Methods for the Determination of Food Additives

The development of analytical methods for the determination of food additives responds to the need to check the stability of the additives during processing and storage or, primarily, to legal requirements such as: (1) establishing whether there are additives present in foods and whether they are permitted, (2) determining their concentration to ensure that they are within the legally established limits, and (3) confirming the absence of illegal additives in foods.

#### Sample Pretreatment: Extraction and Cleanup

The pretreatment of foods before additive determination varies greatly depending on the type of sample (liquid or solid foods, samples with high content of lipids, proteins or carbohydrates) or the analytical

technique employed for the determination of the additive. Often, very simple samples do not require prior treatment or at the most need uncomplicated pretreatments, but most foods need to be treated before the determination of the additive. Frequently, the first step is to use liquid-liquid extraction (LLE) to eliminate interferences. LLE can be simple or repetitive (with the same solvent and then combining all the extracts). The extractant and the extraction method used depend fundamentally on the kind of sample being analyzed. The extraction can be done with a single solvent, principally *n*-hexane, water or acidified water, acetonitrile, dichloromethane, ethanol or methanol, diethyl or petroleum ether, acetone, and chloroform, or with a binary or even ternary mixture of the solvents, containing a very polar solvent, like water or methanol, and other less polar solvents.

However, other matrix compounds are extracted together with the analytes, making it necessary to include an extract-cleanup step. The thoroughness of this step depends on the detection system: if the detector being used is selective enough, an exceedingly thorough cleanup of the extract is not necessary; but if the detector is not very selective, this step must eliminate as many as possible of the coextracts that can interfere in the determination.

Moreover, because the additive concentration in this extract is not sufficient for the detection of legal limits, it is necessary to preconcentrate the analytes. LLE is commonly used to separate additives from their coextracts. Nevertheless, the recent trend is to replace LLE with solid-phase extraction (SPE). It is possible to use SPE as a single cleanup/preconcentration step or as an additional step after LLE. The use of SPE has become popular because of the great variety of polar and nonpolar sorbents and ionic exchange resins that exist. The sorbents most often used to preconcentrate food additives are: RP-C<sub>18</sub>, silica gel, sorbents with amino groups, XAD-2 polymeric sorbent, polyamide and wool.

Supercritical fluid extraction is another technique used to extract food additives. Its main advantages are that it saves both time and solvents; the solvent most often employed is carbon dioxide, for its moderate critical temperature (31°C) and pressure (73 atm). In addition, carbon dioxide is not inflammable, toxic, or very expensive. Methanol is sometimes used as a modifier to adjust the dissolution power of this fluid.

Quite recently, other extraction techniques have been developed and are being employed for the determination of food additives, but are not yet widely used. These techniques include countercurrent chromatography, gel permeation chromatography,

distillation, membrane separation, dialysis and microdialysis, microwave-assisted extraction, solvent extraction assisted by ultrasound, solvent microextraction, solid-phase microextraction, and stir bar sorptive extraction.

It is important to emphasize that specific difficulties arise when extracting antioxidants and preservatives from fatty foods. Most of the permitted antioxidants and preservatives are fat soluble, so it may first be necessary to extract the fat from the food and then extract the antioxidants from the fat. As a result, the determination of these additives implies the removal of triglycerides; the techniques most frequently used to remove triglycerides are saponification of the extracts, esterification of the extracts in the presence of lipase, and the separation of the analytes by preparative liquid chromatography.

### **Determination, Separation, and Detection of Food Additives**

For the determination of food additives several analytical methods are used based on spectroscopic, electrochemical, and separation techniques, the latter with detectors included.

For the determination of individual additives several spectroscopic techniques are normally employed: ultraviolet-visible spectrophotometry, spectrofluorimetry, luminescence, and photoacoustic spectrometry. Sometimes, to increase method selectivity, a combination of spectroscopic techniques is used. Another alternative to determine individual additives are electrochemical techniques: voltammetry, polarography, amperometry, and potentiometry.

However, additives are normally combined to complement and promote their activity; as a result, it is necessary to develop analytical methods for the determination of additive mixtures. Although some spectroscopic and chemical methods are used, it is preferable to use separation methods for this purpose. Most analytical methods used to determine food additives are based on chromatographic techniques, although several recent papers have demonstrated the usefulness of electrophoresis for the analysis of food colors, sweeteners, antioxidants, and/or preservatives. The separation of food colors has received most attention, with a number of articles published on both capillary zone electrophoresis and micellar electrokinetic chromatography.

Thin-layer chromatography, in its normal and high resolution forms, is used for the separation and quantification of additives with minimal sample manipulation. The most common detection technique

is ultraviolet–visible spectrophotometry, although other techniques such as spectrofluorimetry and mass spectrometry are also used.

Liquid chromatography is the preferred technique to determine food additives, which in general are not very volatile and sometimes are thermolabile.

In most of the methods that have been developed, the stationary phase used for the additive separation is a polygosyl-bonded silica reversed-phase sorbent with octadecylsilane functional groups (RP-C<sub>18</sub>), although other stationary phases such as reverse RP-C<sub>30</sub> and ionic-exchange phases have also been used. The detection of additives, after their separation by liquid

chromatography, has been done using ultraviolet-visible, fluorescence, electrochemical, and mass spectrometry detectors.

Gas chromatography, with or without derivatization, is also used to selectively determine individual or mixtures of food additives. The additive separation is done using nonpolar stationary phases consisting

of 100% poly(dimethylsiloxane), intermediate polarity phases consisting of 5% diphenyl–95% dimethylsiloxane or 50% diphenyl–50% dimethylsiloxane, and polar phases consisting of 100% poly(ethyleneglycol). The detection of these analytes is usually done using a flame ionization detector, which is able to detect compounds with  $-CH_3$  groups, or universal detectors like a mass spectrometry detector.

### Identification of Food Additives

When analyzing food additives it is frequently necessary to identify the additives that have been determined quantitatively using the above cited detectors that, while supplying high sensitivity (essential for measuring the established legal limits), are not able to identify these compounds. To confirm the obtained results two strategies are used: on the one hand, the use of detectors that are able to unmistakably identify the analytes; on the other hand, the use of two different detectors to compare their responses against the same mixture of additives.

Mass spectrometry is an excellent tool that can be used coupled to either a liquid or a gas chromatograph to confirm the identity of the additives present in foods. A complete mass spectrum of an additive provides structural information that is unique to the additive. Most of the studies that have been done use the ionization technique for electronic impact to a certain energy (normally 70 eV).

Detection by a diode array detector can be used to confirm the identity of an additive. This detector is usually coupled with a liquid chromatograph to record the ultraviolet–visible spectra for each of the chromatographic peaks so that they can be compared with the spectra of the pure compounds. Moreover, the purity of each of the chromatographic peaks can be checked.

The use of two connected detectors, in succession or in parallel, is widely employed, coupling them to either a liquid or gas chromatograph.

The Association of Official Analytical Chemists (AOAC) publishes reference methods for the analysis of additives in foods. The following **Tables 4–8** summarize the AOAC Official Methods of Analysis applicable to antioxidants (**Table 4**), preservatives (**Table 5**), sweeteners (**Table 6**), color additives (**Table 7**), and emulsifying agents (**Table 8**).

### Introduction

Antioxidants and preservatives are added to foods to retard their deterioration. Antioxidants retard

chemical oxidation of the lipids whereas preservatives retard microbiological deterioration. In the UK, the permitted antioxidants and preservatives are listed in the Miscellaneous Food Additives Regulations (1995). Common allowed antioxidants and preservatives are listed in **Tables 1** and **2**. The allowed additives vary from country to country with

of 100% poly(dimethylsiloxane), intermediate polarity phases consisting of 5% diphenyl–95% dimethylsiloxane or 50% diphenyl–50% dimethylsiloxane, and polar phases consisting of 100% poly(ethyleneglycol). The detection of these analytes is usually done using a flame ionization detector, which is able to detect compounds with  $-CH_3$  groups, or universal detectors like a mass spectrometry detector.

*tert*-butylhydroquinone (TBHQ) and 2,4,5-trihydroxy-butyrophenone (THBP) being allowed antioxidants in the USA.

The Association of Official Analytical Chemists (AOAC) describes several methods for the analysis of antioxidants or preservatives. These include methods developed over many years. Most methods involve analysis by gas chromatography (GC), high-performance liquid chromatography, or spectrophotometry.

Capillary electrophoresis has been shown to be a very versatile technique for the analysis of a wide range of additives including both antioxidants and preservatives. Methods employing mixed micellar electrokinetic chromatography have been reported. However, the AOAC has not yet developed an official method based on this technique.

## Antioxidants

Antioxidants are mainly analyzed by colorimetric methods, liquid chromatography (LC), or GC. Method 965.28 of the AOAC describes qualitative color tests for detecting propyl gallate (PG), nordihydroguaiaretic acid (NDGA), butylated hydroxyanisole (BHA), and butylated hydroxytoluene (BHT). After solvent and aqueous extractions PG forms a pink color with ammonia solution, NDGA forms a blue color with barium hydroxide, BHA forms a red-purple color with Ehrlich reagent (diazobenzene sulfonic acid), whereas BHT is separated by column chromatography and develops a chloroform-soluble pink to red color in the presence of dianisidine (3,3'-dimethoxybenzidine) and sodium nitrite.

PG may also be quantified by a colorimetric procedure in which quantification depends on light absorption at 540 nm, after color development by reaction with ammonium acetate and iron(II) tartrate (AOAC method 952.09).

A reversed-phase LC method can be used for the quantitative analysis of mixtures containing PG, 2,4,5-tri-hydroxybutyphenone (THBP), *tert*-butylhydroquinone (TBHQ), NDGA, BHA, BHT, and 2,6-di-*tert*-butyl-4-hydroxymethylphenol (Ionox-100), as described in AOAC method 983.15. Baseline separation of the seven antioxidants is achieved using a reversed-phase column and stepwise gradient of 30% acetonitrile–acetic acid (95:5; v/v), 70% water–acetic acid (95:5; v/v) changing to acetonitrile–acetic acid (95:5; v/v). Detection of the antioxidants is by ultraviolet (UV) absorption at 280 nm. Octyl gallate, if present, may coelute with Ionox-100, but can be separated by a linear gradient of 30% methanol–acetic acid (95:5; v/v), 70% water–acetic acid (95:5; v/v) changing to methanol–acetic acid (95:5; v/v). Page and Charbonneau determined the antioxidants in a variety of foods by a method similar to this.

BHA and BHT are commonly determined by GC. AOAC method 968.17 describes a procedure for the analysis of these antioxidants in cereals. The antioxidants are extracted with carbon disulfide and analyzed by GC using packed glass columns containing Apiezon L or QF-1 fluorosilicone fluid as

stationary phases. The order of elution from the Apiezon column is BHA, BHT, di-BHA, whereas the order of elution from the QF-1 column is BHT, BHA, di-BHA. Analysis is performed with the oven at 160°C, with BHT eluting in 3–4 min from the QF-1 column and BHA eluting in 3–4 min from the Apiezon column. The analytes are detected with a flame ionization detector.

Gas chromatographic procedures have been described for the determination of several antioxidants. Glass columns packed with OV-17 as stationary phase are able to separate TBHQ, TDPA, PG, THBP, and NDGA. Oil samples containing antioxidants can either be injected onto a precolumn, which prevents the nonvolatile oil entering the analytical column, or alternatively the antioxidants can be isolated by steam distillation or liquid–liquid partition prior to GC analysis. Solid-phase extraction cartridges have been used to remove traces of triacylglycerols remaining after liquid–liquid extraction prior to GC analysis.

Although the standard methods describe the use of packed columns, capillary columns are widely used for the analysis since they improve the resolution of sample components, and reduce inaccuracies in the quantification of antioxidants arising from interference of other oil components. Figure 1 shows the resolution of antioxidants by capillary GC.

**Figure 1** Gas chromatogram of antioxidants. Peaks: 1, 8-quinolinol; 2, BHA; 3, BHT; 4, TBHQ. (Reproduced with permission from Yang M-H, Lin H-J, and Choong Y-M (2002) A rapid gas chromatographic method for direct determination of BHA, BHT and TBHQ in edible oils and fats. *Food Research International* 35: 627–633; © Elsevier.)

Besides the GC analysis of underivatized antioxidants, antioxidants have also been converted to trimethylsilyl ethers, benzoyl esters, trifluoroacetates, and heptafluorobutyl derivatives prior to GC analysis.

Vitamin C (ascorbic acid) and its fat-soluble derivative ascorbyl palmitate also have antioxidant activity under certain conditions. The determination of vitamin C is discussed elsewhere.

## Preservatives

Preservatives have been analyzed by a wide variety of methods including titration, thin-layer chromatography (TLC), GC, LC, and spectrophotometric methods.

### Benzoic Acid

Benzoic acid and its salts may be determined by titration with sodium hydroxide after extraction of the benzoic acid from an aqueous food suspension into chloroform, and evaporation of the chloroform and any acetic acid present (AOAC method 963.19). Vanillin interferes with this determination and a more selective method involves the determination of benzoic acid in an ether extract by UV absorption at 272 nm, as described in AOAC method 960.38. An alternative method of isolating benzoic acid from food involves the use of steam distillation and TLC separation. These sample preparation techniques are used in AOAC method 967.15 prior to the determination of benzoic acid by UV absorption.

A gas chromatographic method may be employed for analysis for both benzoic acid and sorbic acid in food, as described in AOAC method 983.16. The acids are extracted from an acidified aqueous homogenized food sample into ether. The acids are then extracted from the ether solution into aqueous alkali, and after acidification they are re-extracted into dichloromethane. Treatment of the residue with *N*-methyl-*N*-trimethylsilyltrifluoroacetamide converts the benzoic and sorbic acids into trimethylsilyl esters. These esters are then analyzed with a glass column packed with a support coated with OV-1, in a temperature programmed analysis. Phenylacetic and caproic acids are used as internal standards for benzoic and sorbic acids, respectively. An LC method has also been described for analysis of benzoic acid with simultaneous determination of sorbic acid, and methyl, ethyl, propyl, and butyl *p*-hydroxybenzoates. The preservatives were extracted from meat or seasonings with 70% ethanol, and analyzed by reversed-phase LC using a C<sub>18</sub> stationary phase with a linear gradient from 10 to 70% methanol in 1.5% aqueous ammonium acetate and 1.5% aqueous acetic acid.

Good baseline separation of the analytes was achieved in less than 13 min.

The International Dairy Federation has adopted an LC method as a standard method for the determination of the benzoic acid and sorbic acid content of milk, dried milk, yogurt, and other fermented milks (IDF standard 139: 1987). Fats and proteins are removed initially by treatment of the product with aqueous alkali, addition of methanol, and filtration prior to LC analysis.

Ion chromatography has also been described for the analysis of benzoic acid and sorbic acid, together with artificial sweeteners, caffeine, theobromine, and theophylline. The preservatives were analyzed on an anion-exchange analytical column operated at 40°C.

### Sorbic Acid

Sorbic acid may be isolated from cheese by steam distillation from an acidified sample. Oxidation of the sorbic acid by heating in a boiling water bath with acidified dichromate solution, followed by treatment with thiobarbituric acid solution, converts the analyte to a colored product absorbing at 532 nm (AOAC method 971.15). Alternatively, sorbic acid may be determined in dairy products by absorption at 250 nm after treatment of a sample with metaphosphoric acid and extraction into ether, as described in AOAC method 974.10.

### Sulfur Dioxide

Over the pH range of foods (pH 2–7), sulfur dioxide is found as one or more of the species  $\text{SO}_2 \cdot \text{H}_2\text{O}$ ,  $\text{HSO}_3^-$ ,  $\text{S}_2\text{O}_5^{2-}$ , and  $\text{SO}_3^{2-}$ . Acidification is required to allow all sulfur(IV) oxoanions to be determined as sulfur dioxide.

The simplest method available for the determination of sulfur dioxide in foods is iodimetric titration in the presence of starch after addition of acetone, glyoxal, or formaldehyde. Acidification before the titration allows the determination of both free and reversibly bound sulfur dioxide. Amperometric methods for detecting the endpoint allow the method to be extended to colored samples.

A long-established procedure for the determination of sulfur dioxide is the Monier–Williams method in which sulfur dioxide is distilled from an acidified solution and the vapor passes through U-tubes containing hydrogen peroxide which oxidizes it to sulfuric acid. The acidity produced is then titrated with dilute standard alkali. This procedure is preferred to an iodimetric titration when volatile sulfur compounds are present as in mustard, onion, and horseradish. Sulfur dioxide may also be

determined spectrophotometrically by methods based on the reaction between *p*-rosaniline, formaldehyde, and sulfur(IV) oxoanions. This reaction is employed in AOAC method 963.20 for sulfurous acid (total) in dried fruit. The sulfur(IV) oxoanions are extracted into water and treated with sodium tetrachloromercurate solution, before addition of acid-bleached *p*-rosaniline hydrochloride and formaldehyde solution. The absorbance at 550 nm is determined and quantification is achieved by an external standard calibration plot.

Sulfur dioxide in shrimps, orange juice, peas, dried apricots, and dehydrated potatoes may be determined by differential pulse polarography, as described in AOAC method 987.04. The sulfur dioxide is purged with nitrogen from an acidified sample, and collected in electrolyte trapping solution comprising ammonium acetate buffer prior to analysis by differential pulse polarography.

Ion-selective electrodes using a sulfur dioxide gas-sensing membrane probe have been developed into commercial models for the determination of sulfur(IV) oxo-species. A typical procedure for the determination of free sulfur dioxide requires the probe to be immersed in a stirred solution at pH 1, whereas total sulfur dioxide requires the sample to be treated with strong alkali prior to acidification and analysis at pH 1. Molecular sulfur dioxide passes through the membrane into a solution of hydrogen sulfite ion and the pH of the  $\text{SO}_2 \cdot \text{H}_2\text{O}/\text{HSO}_3^-$  buffer can be determined with a glass electrode.

Sulfur dioxide may be determined after removing it from foods by distillation, and titration with sodium hydroxide in the presence of methyl red. GC headspace analysis with a flame photometric detector has also been used for the quantification of this food additive.

LC methods have been developed for the determination of sulfur dioxide. In one procedure, the sulfur dioxide was collected by distillation from strongly acidic solutions of food samples and oxidized to sulfate with hydrogen peroxide. The sulfate solutions were neutralized, diluted, and analyzed by LC with a strong anion-exchange column, and a mobile phase of potassium hydrogenphthalate solution at pH 5.7. UV detection at 280 nm gave a good detection limit of  $\sim 5 \text{ mg kg}^{-1}$ .

Ascorbates, benzoates, sorbates, and sulfites in ground beef may be determined spectrophotometrically in AOAC method 980.17 by extracting the preservatives into aqueous solutions. The ascorbates are determined by the indophenol reaction; benzoates and sorbates are determined by absorption at 225 and 250 nm, respectively, in light petroleum solution; and sulfites are determined at 550 nm after

reaction with *p*-rosaniline in the presence of sodium tetrachloromercurate.

### Nitrates and Nitrites

Nitrates and nitrites occur ubiquitously in nature and are added to some foods, for example, meat products, as preservatives. They inhibit the growth of microorganisms, especially *Clostridia* in canned-comminuted and cured meats.

Nitrite may be determined by its absorbance at 522 nm after extraction from foods such as cheese or flour and reaction with a color reagent comprising sulfanilic acid and 1-naphthylamine in aqueous acetic acid. Nitrate is determined by this method after reduction to nitrites using cadmium in a modified Jones Reductor as described in AOAC method 976.14.

Nitrites and nitrates in meat may be determined by oxidizing nitrite to nitrate with potassium permanganate. The nitrate is then reacted with *m*-xylenol in tungstophosphoric acid. Silver-ammonia solution is added to precipitate all the chloride and excess tungstophosphoric acid present. The nitroxylenol is distilled and determined by UV absorption at 450 nm.

Nitrate may also be determined by LC with an anion-exchange column. A comparison has been made between the traditional method of nitrate determination using a reducing cadmium column and spectrophotometric determination with a reversed-phase LC method with orthophosphoric acid adjusted to pH 3.5 with sodium hydroxide as the mobile phase. A high correlation was observed between the nitrate content determined by the two methods. However, LC was found to be more precise, reproducible, and appropriate for routine work.

Various GC methods have also been developed for the determination of nitrate, but the ions must be derivatized to achieve suitable volatility before GC analysis. Nitrate is commonly determined as nitrobenzene, which can be detected with an electron-capture detector or a thermal energy analyzer at levels of 0.05 or 0.1  $\mu\text{g ml}^{-1}$ , respectively.

Nitrite can be oxidized to nitrate and determined as nitrobenzene, but several alternative derivatization techniques have been developed. Nitrate can be converted into tetrazolophthalazine or the trimethylsilyl derivative of benzotriazole, or the ion can be derivatized with 3,4-dichlorobromobenzene or *p*-bromochlorobenzene by the Sandmeyer reaction. An elegant one-step derivatization procedure involves the reaction of pentafluorobenzyl bromide with nitrite in alkali at 50°C for 90 min. This procedure allows analysis with an electron-capture

detector, and good agreement between this method and spectrophotometric methods has been found.

### Biphenyl, 2-Hydroxybiphenyl, and Thiabendazole

Biphenyl, 2-hydroxybiphenyl, and thiabendazole are used almost exclusively to prevent fungal growth on fruits, usually citrus fruits, after harvesting. Different countries have set varying limits as to the residual levels of these preservatives, which may carry through into the food chain.

Biphenyl is usually determined by chromatographic analysis of an extract prepared using an organic solvent. In the TLC method, biphenyl is located under UV radiation, extracted with methanol, and determined spectrophotometrically at 248 nm. If the silica gel layer is impregnated with the fluorescent indicator GF254, biphenyl can be detected by densitometry. LC analysis with UV detection at 254 nm and fluorimetric detection at 350 nm with excitation at 285 nm are good alternatives. Derivative infrared spectrometry has also been developed as an alternative procedure.

Steam distillation of biphenyl and 2-hydroxybiphenyl has been used to isolate the preservatives prior to analysis by GC. Simultaneous analysis of biphenyl, 2-hydroxybiphenyl, and thiabendazole in an organic extract from homogenized citrus fruits has been achieved with a column packed with FFAP as stationary phase. However, thiabendazole has commonly been converted into the methyl ester or pentafluorobenzyl ester before GC analysis. LC methods are also used for the determination of thiabendazole.

### Introduction

The common understanding of food contaminants is very broad, covering topics as diverse as natural toxins through agrochemical and veterinary drug residues to industrial contaminants and extraneous matter such as glass and metal objects introduced during food processing.

A European Community Council Regulation (No. 315/93) defines a food contaminant as: “any substance not intentionally added to food which is present in such food as a result of the production (including operations carried out in crop husbandry, animal husbandry and veterinary medicine), manufacture, processing, preparation, treatment, packing, packaging, transport or holding of such food, or as a result of environmental contamination. Extraneous matter, such as, for example, insect fragments, animal hair, etc. is not covered by this definition.”

This definition of food contaminants encompasses a very broad range of chemical substances, many of which are covered by other articles in this Encyclopedia, particularly natural toxins, mycotoxins, pesticides, antibiotics, and metals (both individually and collectively). Consequently, this article will give an overview of chemical contaminants in foods, dealing particularly with agrochemical and veterinary drug

residues in food and residues of industrial contaminants, leaving the more in-depth treatment of particular classes of contaminants to the other articles.

Chemical contaminants in food are of concern to the consumer, to food manufacturers, and to regulatory authorities. Contamination of food with chemicals may arise from the use of agrochemicals and veterinary drugs in food production or from environmental pollutants and industrial chemicals during food processing and packaging. A wide variety of analytical techniques are used for the detection and quantitation of contaminants in food ranging from microbiological tests through immunoassays to all forms of chromatography. Analyses for contaminants in foods are characterized by the requirements for intricate extraction/cleanup and for sensitivity. This article describes the methodologies used for contaminant residue analyses in food, covering screening and confirmatory techniques, the range of extraction and clean-up methodologies used, and both specific and multiresidue procedures.

### Major Analytes

The major source of potential contaminants in food is the direct application of agrochemicals to plants and animals and the use of veterinary drugs for treating food-producing animals.

Pesticides, including fungicides, herbicides, and insecticides, are routinely used in most food production to control pests that would otherwise destroy or reduce the food production. Because of the very large

### Introduction

The common understanding of food contaminants is very broad, covering topics as diverse as natural toxins through agrochemical and veterinary drug residues to industrial contaminants and extraneous matter such as glass and metal objects introduced during food processing.

A European Community Council Regulation (No. 315/93) defines a food contaminant as: “any substance not intentionally added to food which is present in such food as a result of the production (including operations carried out in crop husbandry, animal husbandry and veterinary medicine), manufacture, processing, preparation, treatment, packing, packaging, transport or holding of such food, or as a result of environmental contamination. Extraneous matter, such as, for example, insect fragments, animal hair, etc. is not covered by this definition.”

This definition of food contaminants encompasses a very broad range of chemical substances, many of which are covered by other articles in this Encyclopedia, particularly natural toxins, mycotoxins, pesticides, antibiotics, and metals (both individually and collectively). Consequently, this article will give an overview of chemical contaminants in foods, dealing particularly with agrochemical and veterinary drug

residues in food and residues of industrial contaminants, leaving the more in-depth treatment of particular classes of contaminants to the other articles.

Chemical contaminants in food are of concern to the consumer, to food manufacturers, and to regulatory authorities. Contamination of food with chemicals may arise from the use of agrochemicals and veterinary drugs in food production or from environmental pollutants and industrial chemicals during food processing and packaging. A wide variety of analytical techniques are used for the detection and quantitation of contaminants in food ranging from microbiological tests through immunoassays to all forms of chromatography. Analyses for contaminants in foods are characterized by the requirements for intricate extraction/cleanup and for sensitivity. This article describes the methodologies used for contaminant residue analyses in food, covering screening and confirmatory techniques, the range of extraction and clean-up methodologies used, and both specific and multiresidue procedures.

### Major Analytes

The major source of potential contaminants in food is the direct application of agrochemicals to plants and animals and the use of veterinary drugs for treating food-producing animals.

Pesticides, including fungicides, herbicides, and insecticides, are routinely used in most food production to control pests that would otherwise destroy or reduce the food production. Because of the very large

number of these substances used in food production, analyses are mainly multiresidue, directed to particular classes of pesticides such as organochlorine, organophosphorus, or carbamate substances.

Veterinary drugs are used to treat animals for bacterial infections (antibiotics) and parasitic infestations (anthelmintics, coccidiostats), to enhance growth (antibiotics, anabolics, partitioning agents, thyrostats), to control fertility and reproduction (steroid hormones), or to alter behavior (tranquillizers and sedatives). Within each of the drug types there are different classes and methods for residue analysis are typically class specific (e.g., methods for the class of tetracycline antibiotics). In certain cases, multiresidue methods are available that are broader than specific classes.

In many cases, maximum residue limits (MRLs) exist for veterinary drugs and the analytical methods must be capable of measuring below such MRLs. Since MRLs vary considerably, the sensitivity requirements of the various methods also vary widely. Typically, MRLs for veterinary drug residues vary from  $1 \text{ mg kg}^{-1}$  (ppm) to  $1 \mu\text{g kg}^{-1}$  (ppb) (Table 1) or, in the case of banned substances, to 'no detectable residue'. Where 'no detectable residue' is specified, it is common to declare an 'action limit' or a 'limit of decision' for use by regulatory agencies; this is not strictly scientifically based and takes into account other aspects such as the sensitivity of a suitable confirmatory technique and policy requirements.

A wide range of industrial contaminants may occur in food arising from environmental contamination, from food processing procedures, or from food packaging materials. These substances include polychlorinated biphenyls (PCBs), dioxins and heavy metals, nitrosamines, polycyclic aromatic hydrocarbons (PAHs), and acrylamide, and packaging material monomers and plasticizers.

## Sampling and Preparation

### Samples and Sampling

Sampling of food for residue analysis is governed by the rules that apply to all sampling, namely that the analytical sample should contain the residues in the forms and at the levels corresponding to those present in the lot of which the sample is representative. Sampling of food for residue analyses may be very directed (e.g., to establish whether residues of a particular pesticide are present in a particular shipment of fruit) or very broad (e.g., as part of a national monitoring program designed to establish the incidence of use of banned substances in meat-producing animals). For the latter circumstances exact

**Table 1** Maximum residue limits (MRLs) specified by EC Regulation (2377/90) for some veterinary drugs

<i>Veterinary drug</i>	<i>Target tissues</i>	<i>MRL</i> ( $\mu\text{g kg}^{-1}$ )
<i>Anti-infectious agents – chemotherapeutics</i>		
Sulfonamides	Muscle, liver, kidney, milk	100

	Muscle, kidney	0.75
	Milk	0.3

<sup>a</sup> Depending on species.

sampling plans are required which are statistically based so that an accurate representation of the situation may be obtained from the analyses.

The appropriate sample depends to a large extent on the nature of the food. In the case of plant foods such as grain, a composite sample is constructed

from a number of samples taken at specified points throughout the load, as described in ISO Standard 7002:1986. In the case of plant foods such as fruit and vegetables, the composite sample is constructed from individual items selected according to a defined procedure and is described in ISO Standard 874:1980.

In the case of foodstuffs of animal origin, sampling from milk and milk products is covered by a number of ISO standards – 707:1997; 5538:1987; 8197:1988. The purpose of these defined procedures is to ensure representativeness of the sample for a variety of nonhomogeneous and homogeneous solid and liquid, bulk and packaged foods. For meat and edible tissues, samples taken from liver or kidney are usually representative, although there may be differences in residue content between the two sections of the kidney (medulla and cortex). Samples from carcasses are normally taken from the same position (muscle or fat) on each carcass and chosen so as to reduce commercial loss as much as is possible.

Samples of body fluids or excreta are often used to monitor illicit use of prohibited substances or for indirect determination of the presence of contaminants in foods of animal origin. For example, analyses of urine, blood, bile, feces may be used to establish whether specified veterinary drugs have been used on a particular animal. Where well-established ratios exist between the levels of drug residue in body fluids and edible tissues (e.g., sulfadimidine levels in blood or urine and in muscle or kidney), analyses of body fluid samples may be used to indicate the levels in edible tissues.

### **Sample Storage**

Samples of foodstuffs taken for analysis for contaminant residues must be stored in such a way as to prevent deterioration of the sample and reduction in the residue content. In the case of relatively dry samples, such as milk powders, or samples protected by an outer skin, such as fruit and vegetables, storage may be at ambient temperature for short periods or at refrigeration temperature. In the case of most animal food materials, storage at refrigeration temperature is satisfactory if analyses are to commence in the short term, but frozen storage ( $\leq -18^{\circ}\text{C}$ ) is recommended, and is essential for prolonged storage. Even lower storage temperatures of  $-40^{\circ}\text{C}$  to  $-70^{\circ}\text{C}$  may be recommended for certain contaminant residues. Homogenization and division of the sample, for example, where required for contra-analysis, may be performed before freezing to avoid the cycle of thawing-freezing-thawing, which may be detrimental to the stability of some contaminant

residues. However, homogenization may increase the contact between contaminant residues and endogenous enzymes in the sample matrix (e.g., chloramphenicol in liver, the effect of  $\beta$ -lactamase on penicillin). Sometimes, addition of preservatives to the sample, such as the antimicrobial sodium azide or enzyme inhibitors, may be useful but only where these agents do not interfere with the subsequent analysis.

### **Sample Preparation**

The analytical sample is generated as a subsample from the composite or bulk sample. In the case of fruit and vegetables, cutting/chopping of the composite sample, mixing, and subsampling is required. Grains are normally subsampled, and then ground before analysis. Milk and milk powders, being already very homogeneous, usually require simple mixing before an aliquot is taken for analysis. Milk products, such as cheese, require chopping/grinding and mixing before subsampling. Tissue samples are minced/homogenized and subsampled. Urine samples are mixed and may be centrifuged, to remove solid particles, prior to sampling for analysis. Blood may be clotted and serum removed or collected in heparinized containers and the blood cells separated by centrifugation and plasma removed.

## **Residue Analysis**

### **Sample Extraction**

The challenge to the residue analyst is to extract the residue of interest from the sample and to purify the resultant extract to the extent necessary to allow for unequivocal identification and accurate quantification by the selected determination technique. The sample extraction and cleanup procedures are defined, therefore, by the requirements of the determination step. These requirements can vary from as little as no extraction, e.g., use of an intact piece of tissue on an agar plate with a test organism for determination of inhibitory substances; or minimal treatment, e.g., dilution of urine and direct assay for residues of growth enhancing substances by immunoassay; to very extensive extraction and cleanup procedures, e.g., multiple extractions with organic solvent, filtration of extracts, evaporation of combined extracts, liquid-liquid partitioning into acid, alkalization, and liquid-liquid partitioning with organic solvent, neutralization, and multiple liquid-liquid partitioning into organic solvent, evaporation and derivatization, as required in the Association of Official Analytical Chemists (AOAC) method for determination of sulfamethazine residues in tissues by gas chromatography-mass

spectrometry (GC–MS) or gas chromatography-electron capture detection (GC–ECD).

With the exception of some limited assays where determination can be made on the intact or diluted sample, most residue determination procedures commence with extraction of the residue(s) from the sample matrix. Organic solvents are commonly used, with selection of the appropriate solvent being based, largely, on the polarity of the residues of interest. Organic solvents cause denaturation of protein and decrease the interaction between residues and proteins. Aqueous extraction is also used particularly for relatively polar residues and has the advantage that lipids present in the sample matrix are not extracted. Modification of the sample homogenate through pH changes may be necessary to make the residue of interest available to the organic solvent extractant; by adjusting pH, the residues may become largely non-ionized and hence more readily extracted. Typically, solvent-sample ratios of 2:1 to 10:1 are used in the extraction procedure and repeated extractions (two or more) are carried out on the sample. The extraction procedure may be by mechanical blending, by manual (separatory funnel), or mechanical (shaker) mixing, by ultrasonics, or by accelerated solvent extraction, which provides efficient extraction under controlled temperature/pressure conditions. In the case of animal tissues, protease digestion prior to extraction may be used to provide better accessibility of the solvent to the residue molecules and to release residues weakly bound to proteins. Where conjugated forms of residues arise in samples, a deconjugation step using enzymes is undertaken prior to extraction; many residues occur as glucuronide or sulfate conjugates, which, being hydrophilic, are difficult to extract.

Having extracted the residue into the extractant, it may be separated from the matrix material by centrifugation, filtration, freezing of the aqueous phase, or binding of the aqueous phase using anhydrous salts. Where the extract is an organic solvent, the volume may be reduced or brought to dryness, by controlled heating and distillation of solvent or evaporation under nitrogen or vacuum, prior to cleanup of the extract. Where the extract is aqueous, transfer of the residues to an organic solvent by liquid–liquid partitioning or isolation of the residues directly from the aqueous phase by a procedure such as immunoaffinity chromatography may be the first step in cleanup of the extract.

### Extract Cleanup

Cleanup of the extract is undertaken by a range of procedures such as liquid–liquid partitioning or

column chromatography. Liquid–liquid partitioning consists of the intimate mixing of two immiscible solvents such that the residue of interest is accumulated selectively in one phase while certain of the contaminating coextractives are accumulated into the other phase. The classical procedure for liquid–liquid partitioning is by manual mixing in a separatory funnel. A form of liquid–liquid partitioning, sometimes termed liquid–solid partitioning, may also be undertaken on columns or cartridges packed with inert material, such as diatomaceous earth. An aqueous extract is introduced on to the column and distributes over the packing material into which the water is absorbed. When the second solvent (phase) is added to the column, it mixes intimately with the inert material and the residue is extracted from the column.

Some cleanup procedures involve a number of liquid–liquid partitioning steps, typically to remove fat and nonpolar coextractives in one step and polar coextractives in another. Movement from one liquid–liquid partitioning step to another may be by separation of phases, by evaporation of one phase and resolubilization in another solvent, by freezing of an aqueous phase and decanting of an organic phase, or by changing the pH to alter the affinity of the residue of interest for the aqueous phase.

Column chromatography is very widely used as a cleanup procedure. The classical glass column chromatography based on a variety of size-exclusion, polar (normal), nonpolar (reversed phase), and ion-exchange materials has been superseded to a considerable extent by microcolumn cartridges available commercially with a very broad range of packing materials or sorbents. This cartridge-based chromatography, known as solid-phase extraction (SPE) is found as a step in many cleanup procedures for residues in foodstuffs. There have been considerable developments during the last decade both in the range of sorbents and the formats available for SPE. In addition to the classical modified silica reversed-phase sorbents a number of polymeric sorbents have been developed that have multiphase characteristics. Formats for automated SPE, including 96-well plate systems, are available.

Automated systems for size-exclusion, or gel permeation, chromatography are very popular, particularly in pesticide residue analyses. Another form of column chromatography, based on the use of specific antibodies to the analyte(s) of interest, is immunoaffinity chromatography (IAC). In this technique, antibodies specific for one or more analytes are covalently bound to an activated support such as Sepharose, which is then packed in a column (**Figure 1**). This technique is particularly suited for coupling

with aqueous extraction. Dialysis, particularly in an automated format, has been used to separate the analytes of interest from larger-sized coextractives in an aqueous extract. However, this technique has not been applied very widely in residue analysis. Column-switching techniques, whereby semipurified sample extracts may be cleaned-up and/or concentrated on an SPE-type precolumn, prior to automated switching into the flow to a high-performance liquid chromatography (HPLC) analytical column, are being used and further developed (Figure 2).

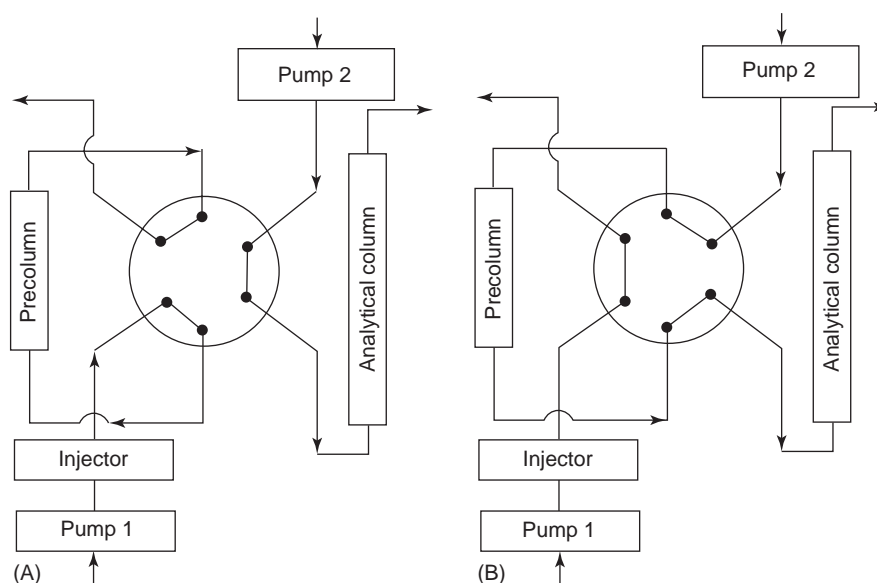

**Figure 1** Schematic representation of immunoaffinity column cleanup. CAP, chloramphenicol (an antimicrobial). (Reproduced with permission from Haagsma N (1990) Sample pretreatment in drug residue analysis. In: Haagsma N, Ruiter A, and Czedik-Eysenberg PB (eds.) *Residues of Veterinary Drugs in Food*, Proceedings of the *EuroResidue Conference*, Noordwijkerhout, The Netherlands, 21–23 May 1990, p. 47. Utrecht: Rijksuniversiteit.)

Some techniques that combine the properties of extraction and cleanup are supercritical fluid extraction (SFE) and matrix solid-phase dispersion (MSPD). Supercritical fluids, i.e., at a temperature and pressure in excess of their critical point, have unique properties for selective extraction of analytes from a sample. Solid samples are mixed with an inert dispersant, such as hydromatrix, and the mixture packed into the cell of the SFE apparatus. The sample is extracted with supercritical CO<sub>2</sub>, with or without addition of organic modifier, and the extracted analytes may be collected inline or offline on suitable adsorbents (Figure 3). Further cleanup of the sample extract may be performed using SPE. MSPD is based on intimate mixing of animal tissue sample with a bonded silica, such as C<sub>18</sub>, and packing of the blended material into a column from which interferences can be eluted by washing with solvents and the analytes eluted using a selective solvent.

### Residue Determination

Residues are determined in the purified extracts by chromatographic or immunochemical techniques. In the chromatographic systems, thin-layer chromatography (TLC), liquid chromatography (LC), and GC, the analytes are separated on plates or columns and determined by colorimetry, by spectrophotometry (ultraviolet (UV), infrared (IR, Fourier transform infrared (FTIR)), by fluorescence, by selective detectors (in GC analysis: ECD, flame photometric (FPD), nitrogen/phosphorus (NPD, TSD), etc.), or by MS. Separations may also be achieved by

**Figure 2** Column switching flow diagram: (A) preconcentration and (B) desorption and chromatographic separation. Reproduced with permission from O'Keefe, *Residue Analysis in Food*, p. 78 (2000) Taylor and Francis.

**Figure 3** SFE system configured for offline analyte collection using a standard 6 ml SPE column and inline using a packed sorbent bed. Reproduced with permission from O'Keefe, *Residue Analysis in Food*, p. 96 (2000) Taylor and Francis.

capillary zone electrophoresis, coupled with UV or MS detectors.

In the case of immunoassays, the binding of the analyte of interest by an appropriate antiserum is the basis of the determination procedure, using radio-labeled, enzyme, or fluorescent markers. Apart from the classical immunoassays in tube or 96-well plate formats, a variety of 'dip-stick' or sol particle systems are available for rapid testing. There have been considerable advances in the application of sensor technologies to high throughput immunoassays for contaminant residues, particularly using surface plasmon resonance (SPR). In SPR-based biosensor systems, antigen-antibody binding reactions on a thin gold film surface may be measured as shifts in the angle of light. Fully automated SPR-based biosensor systems are available – e.g., Biacore<sup>TM</sup> – on which a broad range of rapid analyses have been developed for drug classes such as sulfonamides, coccidiostats, and beta-agonists.

### Quality Assurance

Methods are validated using samples fortified with the analyte of interest at appropriate levels (i.e., normally levels similar to levels found in the samples), levels related to MRLs for permitted substances, or levels related to minimum required performance limits for prohibited or unapproved substances. Following validation of the method and its

**Table 2** Food analysis performance assessment scheme (FAPAS) – contaminants in food

Series Title	Analytes
2 Veterinary drug residues	Sulfonamides, tetracyclines, chloramphenicol, $\beta$ -agonists, nitrofurans, malachite green
4 Aflatoxins	Aflatoxins B, G, M <sub>1</sub>
5 OC pesticides and PCBs	Organochlorine pesticides and PCBs
6 Environmental contaminants	Dioxins, marine toxins, PAHs
7 Metallic contaminants	Pb, Cd, As, Hg, Sn, Fe, Cu, Zn
9 OP and pyrethroid pesticides	Organophosphorus and pyrethroid pesticides
12 Specific migration	Semicarbazide
15 Nitrate analysis	Nitrate, nitrite
16 Patulin	Patulin
17 Ochratoxin A	Ochratoxin A
19 Pesticides	Pesticides
22 Fusariums	Deoxynivalenol, fumonisins, zearalenone

establishment as a routine method in the laboratory, ongoing quality control is maintained by assay of negative and positive controls and/or of fortified samples in the assay. These controls may be generated within the laboratory and are supplemented by external certified reference materials (CRMs), certified for specified levels of the analyte(s) of interest. Such CRMs are produced by the EC Institute for Reference Materials and Measurements, by international and national agencies, such as NIST, and by commercial companies. Quality assurance for residue analysis may be provided also by involvement of a laboratory in appropriate proficiency testing schemes, operated according to ISO standards (ISO Guides 43-1, 43-2: 1997). One example of such is the Food Analysis Performance Assessment Scheme organized by the Central Science Laboratory, UK, which produces samples on a number of occasions each year covering a particular analyte or class of analytes (Table 2). Quality assurance of residue analysis is frequently maintained within a laboratory accreditation framework, to standards such as ISO 17025.

## Quantitative Methods

### Pesticides

This topic is covered in detail elsewhere in the Encyclopedia so only brief mention of relevant methods will be made here. A number of multiresidue procedures for organochlorine (OC), organophosphorus

(OP), and carbamate pesticides are available as standard methods by the AOAC covering both non-fatty and fatty foods. These methods are based on solvent extraction and a variety of column chromatographic cleanup procedures with determination by GC using selective detectors. The International Dairy Federation has approved similar methods for OC and OP pesticide residues in milk and milk products. The AOAC have standard methods for specific pesticides or groups of pesticides that are approved for certain foodstuffs; these methods involve colorimetric, spectrophotometric, or gas chromatographic determination. In the case of methylcarbamate pesticides, a liquid chromatographic method is approved.

### Veterinary Drugs

There are relatively few standard methods for veterinary drug residues although very large numbers of methods are available for the different classes of compounds. The United States Department of Agriculture's (USDA) Food Safety and Inspection Service publish a Chemistry Laboratory Guidebook that, in addition to some AOAC methods, contains a number of validated methods.

Within the European Union, an alternative approach has been adopted to that of standard methods. Commission Decision 2002/657/EC specifies a range of performance criteria for analytical methods to be used to test for the presence of

veterinary drug and other residues in foods of animal origin, under Council Directive 96/23/EC. This decision defines suitable analytical methods and the performance criteria that should be determined for methods, depending on whether they are classified as qualitative or quantitative and screening or confirmatory. Validation procedures are specified for performance characteristics such as specificity, trueness, ruggedness, stability, calibration, recovery, repeatability, reproducibility, decision limit, and detection capability.

Confirmatory methods should preferably be based on MS, providing direct information on the molecular structure of the analyte(s), especially for residues of prohibited substances or substances for which no MRLs are set. However, validated chromatographic methods with specific detectors (e.g., photodiode array, fluorescence) or using two or more different chromatographic separation systems may be used, particularly for contaminants for which MRLs are specified.

There have been major developments in LC coupled with MS (LC-MS/MS) during the last 5–10 years and this technology has been applied very widely for veterinary drug residue analysis (Figure 4). LC-MS/MS is particularly suitable for veterinary drug residues in that derivatization, commonly required for GC-MS analysis, is not necessary. In addition, it can provide robust and sensitive determination.

**Figure 4** Increase in use of mass spectrometry in veterinary drug residue analysis (1990–2002), presentations at major European conferences.

**Antibiotics** The AOAC has listed methods for sulfamethazine residues in swine tissues with determination either by GC-MS or GC-ECD of methylated derivatives and for sulfamethazine (and for the class of sulfonamides) in milk with determination by HPLC-UV. There is an AOAC method for the class of sulfonamide antimicrobials in animal tissues using solvent extraction and liquid partitioning with determination by TLC and fluorimetric scanning. For analysis of tetracyclines, AOAC describes methods based on buffer extraction from tissue samples and SPE (C<sub>18</sub>) cleanup, or metal chelate affinity binding from milk samples, with determination in both cases by HPLC-UV. USDA/FSIS methods include: (1) a method (similar to the AOAC GC-MS method for sulfamethazine) for confirmation of sulfonamide residues in edible tissues using solvent extraction and multiple liquid partitioning with determination of the methylated derivatives by GC-MS; (2) methods for determination and confirmation of chloramphenicol in muscle by solvent extraction, liquid partitioning, and determination of the trimethylsilane (TMS) derivative by GC-ECD and GC-MS, respectively; and (3) a method for determination of the beta-lactam antibiotic amoxicillin by aqueous extraction, cleanup by tricarboxylic acid precipitation, and ether extraction and formation of a fluorescent derivative for determination by LC.

Methods for the determination of residues of most of the important classes of antimicrobials (sulfonamides, chloramphenicol, tetracyclines, beta-lactams, quinolones, and nitrofurans) have been developed based on HPLC or LC-MS/MS determination. These methods are applicable to edible tissues, milk, eggs, urine, and other matrices. The methods typically involve sample workup procedures of solvent extraction and single or multiple SPE cleanup prior to chromatographic determination. For example, extraction of sulfonamides and chloramphenicol may be achieved using aqueous methanol, acetonitrile, or ethyl acetate with cleanup using SPE on reversed phase (e.g., C<sub>18</sub>) and/or cation exchange (e.g., benzenesulfonic acid) sorbents. In the case of tetracyclines, extraction is commonly performed with EDTA/McIlvane buffer and cleanup on C<sub>18</sub>, Oasis HLB<sup>TM</sup> and/or SCX (propylsulfonic acid) SPE cartridges. Determination may be by HPLC with UV detection, by fluorescence detection following postcolumn derivatization, or by MS. In the case of the prohibited nitrofurans, which occur as protein-bound metabolites in edible tissues, methods are directed at releasing these metabolites by acid hydrolysis, derivatization with nitrobenzaldehyde, extraction with ethyl acetate, and determination by LC-MS/MS.

**Growth-enhancing substances** An AOAC method is approved for the growth promoter melengestrol acetate in animal tissues by solvent extraction of fatty tissue and cleanup on a Florisil column with determination by GC-ECD.

Numerous methods have been validated for the determination of anabolic agents (natural and synthetic estrogens, androgens, and gestagens) in edible tissues and in other samples that can be used for food monitoring such as urine, bile, and feces. These methods involve determination of analytes by LC-MS/MS, by GC-MS of suitable derivatives, or by immunological assay, with or without prior LC separation. Typical steps in the extraction, cleanup, and isolation of the analytes are the following:

1. enzymatic hydrolysis of conjugated residues;
2. mechanical homogenization, or enzymatic digestion with proteolytic enzymes;
3. solvent extraction direct, or on diatomaceous earth;
4. cleanup using SPE, e.g., coupled C<sub>18</sub> and amino cartridges for anabolic steroids in urine;
5. analyte isolation by IAC or HPLC;
6. determination of residues by LC-MS/MS, or by GC-MS following derivatization.

Methods for determination of beta-agonists (repartitioning agents) in biological samples involve aqueous extraction using ultrasonics, enzymatic hydrolysis of conjugated residues, solvent extraction, isolation of analytes by IAC, and determination by LC-MS/MS, or of derivatives by GC-MS.

For example, a semiautomated quantitative method is described which is capable of screening and confirmation of 22 steroids in urine. This method involves enzymatic deconjugation followed by dual SPE on C<sub>18</sub> and amino cartridges, using an automated system (ASPEC XL4, Gilson Ltd.). Screening is undertaken by LC-MS/MS, with an electrospray interface, and the column effluent is split between the mass spectrometer and a fraction collector. Where the presence of steroid residues is determined, confirmation is achieved by reanalysis of the collected fraction using either LC-MS/MS, while monitoring additional transition products, or GC-high resolution MS, after derivatization.

**Anthelmintics** The major classes of anthelmintics, or antiparasitic drugs, are benzimidazoles and macrocyclic lactones (avermectins and milbemycins). USDA/FSIS have approved a method based on LC/fluorescence detection for determination of the anthelmintics albendazole and ivermectin in tissues (albendazole extracted with ethyl acetate and cleanup

by liquid partitioning and SPE on a C<sub>18</sub> cartridge; ivermectin extracted with iso-octane and cleanup by liquid partitioning, formation of a fluorescent derivative by heating with imidazole reagent and purification by SPE on a silica cartridge).

Multiresidue methods for benzimidazoles and macrocyclic lactones are applied in many testing laboratories. For example, benzimidazoles may be determined by extraction from tissue with ethyl acetate, removal of fat by liquid/liquid partitioning between acidic ethanol and hexane, cleanup by automated SPE on C<sub>18</sub> or C<sub>8</sub> cartridges, and HPLC chromatography with UV detection at 298 nm. In the case of the macrocyclic lactones, samples are typically extracted using acetonitrile and modified with water–triethylamine prior to purification on C<sub>8</sub> or C<sub>18</sub> SPE cartridges. Residues may be determined, after derivatization, by HPLC with fluorescence detection (excitation 365 nm, emission 475 nm) or determined without derivatization by LC–MS/MS.

**Other veterinary drugs** Other veterinary drugs of importance are the anticoccidial feed additives such as the ionophores, narasin, monensin, salinomycin, apramycin, lasalocid, and nicarbazine. The USDA/FSIS have a method for the major ionophores in tissue samples, which is based on purification of sample extracts by silica gel, alumina, or ion-exchange column chromatography and determination by TLC with detection by bioautography. A number of alternative methods based on immunoassays, biosensor technology, and HPLC have been developed.

Tranquillizers and beta-blockers are important potential contaminants in edible tissues, particularly of pigs, where they may be used to counteract the stress susceptibility of some breeds during transport, which results in poor quality meat and even mortality. Some of these substances are prohibited for use in food-producing animals while others have MRL values set. A simple method for seven of these compounds (azaperol, azaperone, carazolol, chlorpromazine, acepromazine, propionylpromazine, xylazine) involves extraction of kidney or muscle samples with acetonitrile, modification of the extract with a sodium chloride solution (10%), and SPE on an Oasis HLB<sup>TM</sup> cartridge. The eluate (acetonitrile) is evaporated, reconstituted in aqueous acetonitrile, and residues determined by LC–MS/MS, with atmospheric pressure chemical ionization. Two additional steps are incorporated into this method to increase the numbers of sample extracts that may be analyzed without affecting the mass spectrometer source; first, an inline column (Biomatrix<sup>®</sup>) is used ahead of the analytical column to remove any macromolecules in the sample extracts and, second, a switching valve is

used ahead of the mass spectrometer that allows the eluate from the analytical column to pass through the mass spectrometer only during analyte elution.

### Industrial and Processing Contaminants

Typical contaminants of concern are PCBs and polychlorinated dibenzo-*p*-dioxins (dioxins), which are highly persistent environmental contaminants arising from industrial processes, detergents, and disinfectants (especially in milk) that are used in cleaning processes, process contaminants such as PAHs and acrylamide, and food packaging monomers and residual solvents from extraction processes or printed packaging material.

The AOAC standard method for PCBs in foods is similar to that for organochlorine pesticide residues, involving extraction with lipophilic solvent and cleanup by liquid partitioning and column adsorption chromatography with determination by GC with ECD and/or potassium chloride thermionic detector. Current methods for dioxins and coplanar PCBs involve determination by GC coupled with high-resolution MS, to achieve the sensitivity and specificity required. Typically, the sample preparation consists of fat/lipid extraction and isolation of dioxins/PCBs by gel permeation chromatography with extract purification by column chromatography. A method that may be used to screen samples for the presence of dioxins/PCBs is the CALUX<sup>®</sup> cell-based assay. This bioassay technique – Chemical Activated Luciferase eXpression – is based on use of rat or mouse hepatoma cells, modified to show an increased production of luciferase in response to binding of dioxins and dioxin-like PCBs to a particular cell receptor.

Because many detergents and disinfectants contain phosphate, chloride, or iodide, it is difficult to determine the presence of these substances against the naturally occurring levels of these salts in milk or other food. Contamination with detergents or disinfectants is suspected, therefore, by the determination of much higher levels than normally would be found in the food. Ion-selective electrodes are commonly used.

Food packaging monomers and solvents are assayed by headspace GC linked with various detection systems such as FID, AFID, and MS.

Nitrosamines are carcinogenic substances that may form in foods preserved with high levels of sodium nitrite. The AOAC have approved two methods for analysis of nitrosamines in fried bacon, one for volatile *N*-nitrosamines by mineral oil vacuum distillation and extraction into dichloromethane, and the other for *N*-nitrosopyrrolidine by extraction

from a column of Celite with dichloromethane. Nitrosamine levels in the extracts are determined by chemiluminescence, using a gas chromatograph fitted with a thermal energy analyzer.

Acrylamide was identified as a contaminant in heat-treated starchy foods (e.g., potatoes, bread, snack foods) in 2002. Methods for determination of acrylamide in food are based mainly on GC-MS (without derivatization or with derivatization by bromination) or LC-MS/MS. Acrylamide is generally extracted from the food matrix with water, sometimes with defatting using hexane, and cleanup of the extract is achieved using mixed-mode or multiple SPE cartridges.

## Screening Methods

Apart from the methods described above that are used for monitoring of residues in food, meat and milk supplies are assayed routinely for the presence of antimicrobial or 'inhibitory' substances.

In the EC the microbiological 'Four Plate Test' method is used widely as a screening technique for antimicrobial residues in edible tissues (mainly kidney). The principle of this method is a measurement of the extent of inhibition of the growth of test organisms due to the presence of antimicrobial residues in the tissue sample. Modifications and extensions of this methodology have been developed such as a single plate New Dutch Kidney Test and a 12-plate antimicrobial residue identification procedure used in Denmark. A tube-based test, the Premitest<sup>TM</sup>, also uses the principle of inhibition of growth of a test organism but with a colorimetric endpoint, similar to the widely used tests for antimicrobial residues in milk. A sample of fluid is obtained from the tissue sample and incubated in the tube, containing agar seeded with the test organism and a colored substrate sensitive to lowering of pH caused by microbial growth. Presence of inhibitory substances (antimicrobial residues) in the tissue fluid prevents growth of the test organism with no consequent lowering of pH and color change.

The USDA/FSIS have a number of rapid tests for determining the presence of antimicrobial substances in carcasses or in live animals. The 'swab test on premises' and the 'live animal swab test' are developed for kidney (or liver) and urine samples, respectively, using an inhibition agar plate assay. The 'sulfa on site' test is used on farm or at slaughter plant to screen samples of serum, urine, or feed for sulfadimidine residues. The test is based on TLC and uses well-defined ratios between concentrations of sulfadimidine in serum or urine and in edible tissues

to establish whether the concentration in edible tissues is above the MRL of 100  $\mu\text{g kg}^{-1}$ .

Enzyme immunoassays, in a card-test format, are also used for screening carcasses by testing of urine for specific antimicrobial residues such as sulfadimidine and chloramphenicol. The sol particle immunoassay uses adsorption of specific antibodies to dyed colloidal particles (e.g., carbon) as a mechanism for making directly visible the presence of residues (i.e., antigen) in the sample. A lateral flow membrane device is used to identify residue-positive samples through the absence of color formation at the test capture zone (Figure 5).

Milk samples are screened for the presence of antimicrobial residues with inhibition tests in different formats and using a variety of test organisms. Specific antimicrobial identification tests, based on more extensive inhibition tests, enzymatic tests, immunoassays, and receptor assays (Table 3) are also used for milk samples. These tests show considerable

Positive result

Negative result

Sulfonamides	–	–	0.1–1	1	0.01

variation in sensitivity for different classes of antimicrobials and for individual antimicrobials within a class.

### Limitations of Current Analytical Procedures

The aim and purpose of residue analysis for contaminants in food is to ensure the safety of food to the consumer. Because of the large number of potential contaminants and the relatively difficult, expensive, and lengthy procedures required for residue analysis in complex matrices such as food, it is difficult to achieve this aim. Multiresidue procedures, use of a combination of screening and confirmatory techniques, use of robotics and automated systems, and soundly based statistical sampling are all factors that contribute to enhanced control of food safety.

Particular problems are (1) the need for sensitive, multiresidue techniques, giving equivalent, high recovery for a range of analytes of diverse chemistry, (2) the difficulties associated with extracting and determining polar metabolites and/or bound residues, and (3) the inability of the analytical procedures to keep pace with food manufacturing. Real-time and/or online analysis, based on highly automated systems, has the potential for solving some of these problems. In other aspects of food analysis (e.g., near-infrared spectroscopy for online compositional analysis) such systems have been developed. Biosensor-based techniques offer good possibilities here.

In the area of contaminants in food, developments in automated systems using rapid extraction and cleanup based on SPE, IAC, etc., and determination by MS offers the possibility for real-time and multiresidue analyses.

### Water

Water determination is one of the most important and frequent measurements in the processing and analysis of foods and responds to different necessities. The first is commercial because it is more profitable to buy products based on their dry weight. The second one is legal because for hygienic and commercial reasons the law limits the water content in many foods. The third reason is technological: several processes of industrial transformation need to know this value. Finally, the fourth reason is analytical because the food composition is generally expressed with respect to dry matter to facilitate comparison between samples.

The water content of foods varies enormously, as can be seen in **Table 1**. Water is the main component in most foods. It constitutes the medium in which chemical reactions occur and is one of the substrates in hydrolysis. So, eliminating water, or immobilizing it by increasing sugar or salt concentration, inhibits many reactions and the development of microorganisms, thereby increasing food shelf-life. Water also contributes significantly to food texture because of its physical interactions with proteins, polysaccharides, lipids, and salts.

Knowing the water content is not enough to evaluate food stability as foods with similar water content differ in their perishability. Because water activity is a very important factor in the stability and quality of foods, it is frequently measured along with water content. The water activity ( $a_w$ ) of a product in equilibrium with air, in an airtight container at a given temperature and pressure, is defined as the ratio of the partial pressure of water in the air in equilibrium with the product to the vapor pressure of pure water at the same temperature and pressure. Foods with  $a_w$  values between 0.2 and 0.4 are most stable (**Table 2**). The quality of these foods is practically unspoiled by microorganism development, nonenzymatic browning, or lipid autooxidation. Intermediate moisture foods ( $a_w$  value between 0.6 and 0.9) are protected against most of the alterations produced by microorganisms. However, most fresh foods have an  $a_w$  value of 0.97, being susceptible to alteration.

Water in foods is found in three different forms: free, absorbed, and bounded. The ease with which water is eliminated from food depends on the form of the water. To ensure similar results between different water determination methods, standard methods have been developed in which work conditions are specified. In each case the precision of the analytical results must be checked in order to decide if their precision can be substantially improved by using other methods.

### Methods for the Determination of Water in Food

When determining water some precautions must be taken to minimize the losses and gains of moisture that can be produced during sampling and sample preparation. In general, any exposure of the sample to open air and heating of the sample by friction during homogenization should be minimized. During storage the empty space in the sample container must be kept to a minimum because water is transferred to this space to equilibrate water content. It is also necessary to minimize temperature fluctuations because water migrates to the coldest part of the sample. To reduce this potential error, homogenization of the sample is required before its analysis.

Choosing an analytical method depends on the expected water content, volatility or sensitivity to heat of other food components, instrument availability, speed requirements, necessary accuracy, and aim of the analysis.

‘Water content’ is defined as the amount of water lost by a food when it reaches the true equilibrium against zero water vapor pressure. From this definition arises a quantification method of water content called the absolute reference method, a determination that is only possible in specialized laboratories. The food industry only uses practical reference methods, calibrated against the absolute reference method. Moreover, water content standards are not available because a product’s water content depends on the humidity and temperature of the environment, which makes participating in intercomparison exercises between laboratories essential for detecting possible experimental errors.

The Association of Official Analytical Chemists (AOAC) publishes reference methods for the analysis of moisture in foods. Some of these methods are summarized in **Table 3**.

**Table 1** Water, macroelement (calcium, magnesium, phosphorus, potassium, and sodium) and oligoelement (iron, zinc, copper, manganese, and selenium) content in some foods

Food	Amount in 100 g of edible portion

**Absolute Reference Methods**

Among these methods, the Karl Fischer method is the most used. It is a chemical method based on iodine reduction by sulfur dioxide in the presence of water.

The sample is titrated with the Karl Fischer reagent, consisting of a mixture of sulfur dioxide, iodine, and pyridine in methanol. Because pyridine has an unpleasant odor and is toxic, it has been replaced by imidazole, and the methanol has been replaced by

methoxymethanol to stabilize the reagent. The method is precise because the water is determined specifically and selectively by chemical reaction. Moreover, this method determines both free and bounded water.

### Practical Reference Methods

This section examines oven-drying methods. In these methods the sample is heated under specific conditions and the weight loss is used to calculate the water content of the sample. For this determination three types of ovens can be used: convection, forced draft, and vacuum. The determined water quantity is highly dependent upon the type of oven used, the conditions inside the oven, and the time and temperature of drying.

Excess errors can be produced in these analyses due to the loss of volatile compounds different from

water (acids, alcohols, esters, and aldehydes) and to water formation in oxidation and nonenzymatic browning reactions. On the other hand, other errors can be produced as a consequence of not allowing enough time or temperature to evaporate all the water from the sample.

These methods are simple and can analyze many samples simultaneously. The analysis time can be between a few minutes and 24 h. Recently other thermic methods have been developed that use microwave ovens, infrared lamps, halogen lamps, or ceramic heating elements, which reduce analysis time.

To complete the analysis, distillation procedures must also be considered. These techniques consist in the codistillation of sample water with a high-boiling point solvent that is immiscible in water (toluene, xylene, benzene). The distilled mixture is collected, and the sample volume is measured. These methods produce fewer losses by food decomposition than does oven drying at high temperatures. However, measuring by water volume can be less exact than measuring by weight.

Table 4 compares some of the methods used to analyze water in food by principle, type of sample, and analysis time, including some methods based on the physical characteristics of water in food.

### Methods of Determination of Water Activity in Foods

Methods used to measure water activity can be direct and absolute or indirect and calibrated with regard to the former.

**Table 2** Typical water activity of some foods

<i>Food</i>	<i>Water activity (<math>a_w</math>)</i>
Fresh meat and fish	0.95–1.00
Bread	0.95
Cheese	0.90–0.95
Margarine	0.85–0.90
Salami	0.80–0.85
Jams and jellies	0.80
Dried fruits	0.70–0.80
Nuts	0.65–0.75
Honey	0.60–0.65
Cookies	0.30
Milk powder	0.20
Dried vegetables	0.20

**Table 3** Official AOAC analysis methods applicable to moisture

<i>AOAC method</i>	<i>Food</i>	<i>Analytical technique</i>
931.04	Cacao products	Gravimetry
977.10; 984.20; 967.19	Cacao products; oils and fats; dried vegetables	Karl Fischer titrimetry
935.29	Malt	Gravimetry – convection oven
920.116; 984.25	Butter; frozen potatoes	Convection oven
981.05	Malting barley	Convection oven – forced-draft oven
925.45	Sugars	Convection oven – vacuum oven
948.12	Cheese	Steam bath + forced-draft oven
926.07	Macaroni products	Forced-draft oven – vacuum oven
950.46	Meat	Air drying – vacuum oven
968.11; 979.12; 927.05; 926.08; 934.06; 962.12; 920.186; 977.21	Roasted coffee; dried milk; cheese; dried fruits; oils and fats; maple products; corn syrups and sugars	Vacuum oven
969.38	Honey	Vacuum oven – refractometry
977.11	Cheese	Microwave oven
985.14	Meat and poultry products	Rapid microwave oven
969.19; 986.21	Cheese; spices	Distillation
978.13	Milk	Vapor pressure osmometric (VPO) method
972.20	Prunes and raisins	Moisture meter

**Table 4** Comparison of methods used to determine water in foods

<i>Method</i>	<i>Principle</i>	<i>Nature of sample</i>	<i>Analysis time</i>
Karl Fischer	Chemical reaction of the water	All foods, especially foods very low in moisture or high in fats and sugars	5 min
Convection oven	Removal of water and weight of the remaining solids	Not valid for foods that contain volatiles or have components that undergo chemical reactions at high temperatures	0.75–24 h
Forced-draft oven	Removal of water and weight of the remaining solids	Not valid for foods that contain volatiles or have components that undergo chemical reactions at high temperatures	0.75–24 h
Vacuum oven	Removal of water and weight of the remaining solids		3–6 h
Distillation	Separation of water from the solids and volume measurement	Valid for foods that contain volatiles	
Dielectric and conductivity	Change in capacitance or resistance to an electric current that passes through the sample	Foods that contain less than 30–35% of water	
Hydrometry	Relationship between specific gravity and moisture content	Liquid samples: drinks and sugar solutions	
Refractometry	Water in the sample affects light refraction	Liquid samples, condensed milk, sugar solutions, fruits, and fruit products	
Infrared drying Near-infrared spectroscopy	Penetration of heat into the sample Specific absorption of near-infrared radiation (1400–1450, 1920–1950 nm) by the water molecules of the food		10–25 min

### Absolute Methods

These methods are based on measuring air temperature in equilibrium with a product and some other air characteristic like water content, wet bulb temperature, or dew temperature. With these data and the use of an enthalpy diagram of moist air or tables, its hygrometric level can be measured and thus the  $a_w$  value of the product in equilibrium with this air. There are chromatographic, psychometric, and manometric methods.

### Calibrated Methods

These methods use mechanical probes or hygrometers that respond to the variations in the relative humidity of air that are caused by variations in dielectric resistance or capacity. These probes directly measure the relative humidity of air, and the most commonly used is lithium chloride. In general, these methods require frequent calibration and should only be used within a narrow  $a_w$  range.

On the other hand, the reference salts method can indirectly determine the  $a_w$  value of a product using graphic interpolation. This method consists in introducing an aliquot of the sample in an airtight container where different saturated saline solutions or dilutions of sulfuric acid are placed, creating a relative humidity and therefore a known  $a_w$  value. Once equilibrium has been reached, the samples are weighed and the weight variations are represented

according to relative humidity. An interpolation of the curve obtained this way allows the determination of relative humidity and, by extension, the  $a_w$  value of the food.

### Importance of Minerals in the Diet and in Processing Food

Minerals are the inorganic elements constituting foods (excluding carbon, hydrogen, oxygen, and nitrogen) that remain as ashes when foods are incinerated. They are significant for their nutritional value, toxicological potential, and interaction with the texture and processing of foods. For these reasons it is necessary to know and control their concentration levels in foods.

Among the 50 known minerals, between 15 and 20 minerals are natural components of foods that are part of at least one vital biological system of a plant or animal. Some of them are denominated macroelements because of their abundance in foods; these include calcium, phosphorus, sodium, potassium, magnesium, and chlorine. Others are called oligoelements or trace elements due to their minimal concentration; among these are iron, iodine, zinc, copper, chromium, manganese, molybdenum, fluoride, and selenium.

Minerals are divided into two categories according to their biological importance: those with a

known biological role, called essential minerals, and those with an unknown biological role, referred to as nonessential minerals. Some minerals in the nonessential group are being investigated because there is some evidence that they have a biological function, although this biochemical role is not yet clear. The nonessential minerals being investigated are vanadium, tin, nickel, arsenic, and boron. There are also toxic elements, which should be avoided in the diet. This group includes lead, mercury, cadmium, and aluminum. Some essential minerals, like fluoride and selenium, are known to be harmful if consumed in excessive quantities, even though they have biochemical functions that are beneficial when consumed at safe levels.

Some minerals are found naturally in foods in variable amounts and can be modified, or others can be added, during industrial processing of food. **Table 1** indicates the amounts of some of the macro- and microelements that can be found in various raw and processed foods. Moreover, almost all these minerals can be found as pollutants in foods due to environmental or industrial factors, and are analyzed for hygienic reasons, and not as natural components of foods.

## Food Treatments Prior to Mineral Analysis

There are various methods of mineral determination available, and they can be used according to the analytical characteristic that best suits the objectives of the analyst: accuracy, sensitivity, detection limit, specificity, and interferences. Other factors to take into account are the costs of the complete analysis, instrumental availability, and time necessary for analysis.

Before mineral analysis it is usually necessary to treat the sample to ensure that the sample is homogeneous and also to prepare it for the analytical procedure that follows. Various processes may be necessary, but among the most important is sample mineralization, often associated with the need to destroy organic matter present in the sample and always necessary to make the sample soluble. Moreover, the treatment of a sample may entail reduction and homogenization of its size or elimination of interferences. In any case, contamination of the sample or loss of volatile compounds may occur during these steps of the analytical process, affecting the quality of the analytical results.

### Mineralization

Mineralization is usually a crucial step before the analysis of specific minerals because most analytical

methods require that minerals be freed from their matrix. Nevertheless, some analytical techniques, such as near-infrared spectroscopy, sometimes allow mineral estimation without destroying the carbon matrix that constitutes foods.

The destruction of the matrix, generally organic matter, can be done by wet or dry ashing. The selected mineralization procedure depends on what the ashes will be used for and on limitations based on cost, time, and number of samples.

Dry ashing, consisting in incinerating the sample at high temperatures (450°C or higher) in a muffle furnace, converts most minerals into oxides, sulfates, phosphates, chlorides, and silicates. Before measuring the analytes, the residuum is redissolved in a minimal amount of acid and is diluted with distilled water to a known volume. It is a safe method that does not require the addition of a reagent, and once ignited it requires little of the analyst's attention, allowing the treatment of many crucibles simultaneously. The main disadvantage of this method is the long treatment time (12–18 h). Moreover, some elements such as selenium, lead, and mercury can partially volatilize with this procedure. For this reason alternative methods must be used to determine these minerals.

In wet ashing, organic matter is oxidized by the addition of acids and oxidants or their combinations. A strong oxidant such as concentrated nitric acid, sulfuric acid, or perchloric acid is needed to destroy organic matter. In general, reagent mixtures are chosen in accordance with the type of food and the quantification method. Perchloric acid is an excellent oxidant, but its use runs the risk of forming explosive organic perchlorates if the mixture dries completely. Some precautions must be followed when fat-rich foods are treated.

Minerals remain in solution during wet digestion without volatilization losses because the temperatures used are lower than in dry ashing. The oxidation time is short and requires a hood, hot plate, long tongs, and safety equipment. However, this method requires the continual attention of the operator, uses corrosive reagents, and only a reduced number of samples can be treated simultaneously. If perchloric acid is used in the wet digestion, all work must be done in a perchloric acid fume hood.

Microwave radiation systems are now available that accelerate the mineralization process substantially. This process has obvious advantages in reducing decomposition time, acid needs, and the risks of contamination or foaming.

Other alternatives include closed reactor digestion at a high temperature and pressure; combustion in a vessel containing oxygen; the Shöniger method,

which is especially suitable when determining halogens and sulfur; or combustion in an oxygen–argon plasma at a low temperature.

### **Other Pretreatments**

Most solid foods must be ground up in order to obtain a homogeneity compatible with the previously described procedures. In this process it is necessary to adjust the grinding fineness according to the mineralization method that is going to be used. Dry ashing needs particles of diameter between 0.5 and 1 mm to avoid losses by mechanical drag during the incineration. Oxygen combustion methods and especially direct fusion methods need a grade of fineness that avoids particle volatilization losses and artificial enriching of samples.

According to their nature, the ground and homogenized samples are stored cold or at room temperature, in airtight containers made of a material that does not allow the transfer of materials between the container and the product. Generally, a polyethylene or Teflon container is a good solution.

On the other hand, mineralized and solubilized samples sometimes need treatments that eliminate interferences. Factors such as pH, sample matrix, some pretreatments, or the incorporation of a reagent can interfere with the ability of an analytical method to quantify a mineral. In this situation, it is common to turn to the use of masking reagents or separation processes using selective precipitation techniques, liquid–liquid extraction, ion-exchange resins, etc.

### **Sample Contamination**

One of the biggest problems that can occur during mineral analysis is contamination of the sample. The selection of the equipment used to treat the samples is closely related to the mineral that is going to be quantified. Stainless steel enriches the sample in chromium and nickel; agate mortars and mills notably increase the calcium content of the ground product, etc. Teflon has some important advantages, but due to its low resistance to abrasion not all treatments can be done using this material. Sometimes glass is inadequate; this must be taken into account when determining sodium because the glassware used may enrich the solution. Additionally, the repetitive use of glassware can be a contamination source, and for this reason glassware used in sample preparation and analysis must be cleaned scrupulously using acids and the purest water.

Since solvents can contain large amounts of minerals, it is necessary to use the purest reagents and distilled–deionized water to analyze minerals. As

reagents can be very expensive, a possible alternative is to work with a reagent blank or a sample of the reagents used in the sample analysis in the same proportion as in the sample but without the mineral that is going to be analyzed.

## **Methods of Determination of Minerals in Foods**

### **Chemical Methods**

The determination of food minerals can be done using chemical methods. Among them, volumetric methods stand out because they are fast and inexpensive while still being adequately precise. Their main disadvantages are that they have low sensitivity and selectivity.

Ethylenediaminetetraacetic acid (EDTA) complexometric titrations are based on the fact that many metallic ions form stable complexes with this tetradentate ligand, EDTA. The endpoints are detected using complexing agents capable of forming complexes with the metallic species to be determined and having lower coordination constants than those of the complexes that are formed with EDTA and that also have different colors in their free and complexed states.

In precipitation titrations the titration reaction produces an insoluble precipitate. Despite the many known precipitation reactions, very few of them have the necessary requirements to be the basis of a volumetric method. Determining chloride using silver ion precipitation, using several methodologies, is the most appropriate application of this group of titrations.

The most important applications of these methods in food analysis are limited to the determination of certain metals such as calcium in water and beer or chlorides in different types of samples. Table 5 lists some methods used to determine food minerals based on volumetry.

### **Molecular Absorption Spectrophotometry**

These methods, which include colorimetric methods, are based on the measurement of radiation absorption by molecular species at a specified wavelength. In mineral analysis, the absorbent species are usually compounds, mostly coordination complexes, formed in a reaction between the mineral and a chromogen ligand. These methods are more sensitive and selective than the previously discussed methods. Some of the methods that use ultraviolet (UV)–visible spectrophotometry can be combined with dynamic techniques like flow injection systems or with a previous separation using liquid chromatography,

**Table 5** Mineral determination using methods different from atomic spectroscopic methods

<i>Mineral</i>	<i>Foods</i>	<i>Pretreatments</i>	<i>Analytical technique</i>
<i>Titrimetry</i>			
Chloride	Oils	Dry ashing	Precipitation titrimetry
Calcium	Legumes	Wet ashing (HClO <sub>4</sub> :HNO <sub>3</sub> )	EDTA titrimetry
Calcium	Tubers	Lyophilization, dry ashing	EDTA titrimetry
<i>Colorimetry</i>			
Phosphorus	Eggs, vegetables		
Phosphorus	Oils, yogurts, infant foods, fishes, grains, nuts, vegetables, tubers, fruits	Dry ashing	
Phosphorus	Meat, legumes	Wet ashing (HNO <sub>3</sub> :H <sub>2</sub> SO <sub>4</sub> :HClO <sub>4</sub> )	
Phosphorus	Fish, grains, legumes	Wet ashing (HNO <sub>3</sub> :HClO <sub>4</sub> )	
Phosphorus	Grains	Wet ashing (20% HCl)	
Phosphorus	Nuts	Wet ashing (HNO <sub>3</sub> :H <sub>2</sub> SO <sub>4</sub> )	
Iron	Wine	Wet ashing (HNO <sub>3</sub> :HClO <sub>4</sub> )	
Iron	Tubers	Lyophilization, dry ashing	
Iodine	Dairy products	Dry ashing	
Boron	Fruits	Dry ashing	
<i>Electroanalytical techniques</i>			
Selenium and lead	Wine	Wet ashing (HNO <sub>3</sub> :HClO <sub>4</sub> )	Voltametry
Selenium	Vegetables	Wet ashing (HNO <sub>3</sub> :HClO <sub>4</sub> )	Voltametry
Fluorine	Grains		Voltametry
<i>Chromatography</i>			
Sodium, potassium, magnesium, and calcium	Dairy products	Dry ashing	Ionic chromatography
Selenium	Nuts	Wet ashing (HNO <sub>3</sub> :H <sub>2</sub> SO <sub>4</sub> )	Gas chromatography – mass spectrometry
<i>Other techniques</i>			
Sulfates	Oils	Dry ashing	Turbidimetry
Manganese, bromine, cobalt, vanadium, arsenic, antimony, copper, selenium, aluminum, and lanthanum	Tubers		Neutron activation analysis

allowing the quantification of many elements simultaneously. **Table 5** summarizes some of the main colorimetric methods used regularly in mineral analysis.

### Atomic Spectroscopy

These techniques are based on the atomization of the analyte present in a solution, using a flame or a plasma. The amount of an element present in the sample is determined from the absorption or emission of the visible or UV radiation of its atoms in the gaseous phase. The high sensitivity and selectivity that can be achieved with these techniques and the increasing necessity to respond to requests for mineral quantification in foods at trace levels explain the increasing use of some of the atomic absorption and emission spectroscopic techniques. **Table 6** summarizes some

methods applicable to the determination of minerals using atomic spectroscopy.

Among atomic emission spectrometry (AES) methods, the classic flame photometric technique is still favored for determination of sodium and potassium in foods.

The use of an inductively coupled plasma (ICP) allows temperature and stability conditions that eliminate most of the interferences found in combustion sources. The sensitivities that can be obtained and the speed of this technique, which can be used to determine several elements simultaneously, make it in an interesting, although expensive, alternative for the analysis of metals found in foods. Coupling ICP with a mass spectrometer gives the best analytical results, although it is currently a technique restricted to specialized laboratories.

**Table 6** Mineral determination using atomic spectroscopic techniques

<i>Mineral</i>	<i>Foods</i>	<i>Pretreatments</i>
<i>Flame photometry</i>		
Sodium, potassium and calcium	Honey	Infrared lamp drying, dry ashing
Sodium and potassium	Oils, vegetables, fruits, yogurts, fish	Dry ashing
Sodium, potassium, and calcium	Grains	
Sodium and potassium	Meat	Wet ashing ( $\text{HNO}_3\text{:H}_2\text{SO}_4\text{:HClO}_4$ )
<i>Flame atomic absorption spectrometry</i>		
Sodium, potassium, zinc, iron, calcium, and copper	Honey	Wet ashing ( $\text{H}_2\text{SO}_4\text{:HNO}_3$ )
Zinc, cadmium, and lead	Honey	Microwave drying, dry ashing
Iron	Wine	Wet ashing ( $\text{HClO}_4\text{:HNO}_3$ )
Iron	Wine	Without treatment
Manganese, chromium, iron, nickel, and copper	Juices	Wet ashing ( $\text{H}_2\text{SO}_4\text{:HNO}_3$ )
Cadmium, copper, chromium, cobalt, iron, nickel, lead, and zinc	Beverages, dairy products	Dry ashing
Copper, iron, and zinc	Milk	Wet ashing ( $\text{HNO}_3\text{:H}_2\text{O}_2$ )
Copper, iron, zinc, and manganese	Yogurts	Dry ashing
Calcium, magnesium, and zinc	Yogurts	Dry ashing
Copper and zinc	Vegetables, fruits, meat, fish, legumes, cereals, spices, dairy products, tubers, sweeteners, canned foods	Dry ashing
<i>Copper and zinc</i>		
Sodium, potassium, calcium, magnesium, iron, zinc, manganese, and copper	Fats, oils	Wet ashing ( $\text{HNO}_3\text{:HClO}_4$ )
Cadmium and lead	Fish	Wet ashing ( $\text{HNO}_3\text{:HClO}_4$ )
Iron, zinc, aluminum, titanium, and vanadium	Fish	Wet ashing (30% $\text{H}_2\text{O}_2\text{:HNO}_3$ )
Selenium, lead, and cadmium	Baby foods	Wet ashing ( $\text{HNO}_3\text{:H}_2\text{SO}_4$ ) 0.1% Triton X-100 + 1% $\text{HNO}_3$ + 30% $\text{H}_2\text{O}_2$
Cadmium, cobalt, chromium, copper, iron, manganese, molybdenum, nickel, lead, and zinc	Seafood	Wet ashing ( $\text{HNO}_3$ , $\text{H}_2\text{O}_2$ )
Cadmium, calcium, iron, magnesium, manganese, and zinc	Meat	Wet ashing ( $\text{HNO}_3\text{:H}_2\text{SO}_4\text{:HClO}_4$ )
Lead, cadmium, iron, copper, manganese, zinc, and cobalt	Mushrooms	Wet ashing ( $\text{HNO}_3\text{:H}_2\text{SO}_4\text{:H}_2\text{O}_2$ )
Copper, magnesium, lead, sodium, silver, bismuth, manganese, nickel, lithium, cobalt, antimony, calcium, zinc, iron, chromium, aluminum, and potassium	Mushrooms	Wet ashing ( $\text{HNO}_3\text{:HClO}_4\text{:HCl}$ )
Potassium, sodium, calcium, magnesium, iron, manganese, copper, and zinc	Vegetables	Wet ashing ( $\text{HNO}_3$ )
Sodium, potassium, magnesium, zinc, and copper	Tubers	Lyophilization, dry ashing
Calcium, magnesium, iron, zinc, copper, and manganese	Fruits	Microwave drying, wet ashing ( $\text{HNO}_3$ : 30% $\text{H}_2\text{O}_2$ )
<i>Inductively coupled plasma</i>		
Aluminum, barium, calcium, copper, iron, potassium, iron, copper, iron, potassium, magnesium, manganese, sodium, strontium, and zinc	Beverages	Without treatment
Calcium, cobalt, copper, chromium, iron, magnesium, manganese, molybdenum, sodium, zinc, silver, aluminum, arsenic, barium, beryllium, cadmium, mercury, nickel, lead, antimony, tin, strontium, titanium, thallium, uranium, and vanadium	Milk, flour	Microwave drying, dry ashing
Calcium, phosphorous, magnesium, sodium, potassium, aluminum, iron, zinc, and copper	Seafood, meat	Dry ashing
Chromium, iron, manganese, selenium, and zinc	Vegetables	Wet ashing ( $\text{HNO}_3\text{:HClO}_4$ )
Aluminum, boron, calcium, iron, magnesium, phosphorus, potassium, sodium, and titanium	Fruits, fruit products	Microwave drying, wet ashing ( $\text{HNO}_3$ )
Hydride/cold vapor		
Selenium	Flour, flour products	Wet ashing ( $\text{HNO}_3\text{:HClO}_4\text{:H}_2\text{SO}_4$ )
Selenium	Milk	Wet ashing ( $\text{HNO}_3\text{:HClO}_4$ )
Mercury	Fish	Wet ashing ( $\text{HCl}$ , $\text{HNO}_3$ , $\text{H}_2\text{SO}_4$ )
Mercury	Mushrooms	Wet ashing ( $\text{HNO}_3$ )

Atomic absorption spectrometry (AAS) is the most common technique for the determination of metals in food products.

Most commonly used instruments use a flame (flame AAS (FAAS)) produced by combustion of an air/acetylene or dinitrogen oxide/acetylene mixture. The few interferences are easy to avoid, and the sensitivities that are reached are adequate for the metals of greatest interest to the food industry. Variants of this technique, such as the coupling of hydride generation (HG) systems (HG-AAS), increase its scope to higher-sensitivity determination of elements like selenium, arsenic, tin, and other elements that form hydrides. In a similar vein, the determination of mercury using the cold vapor technique should be highlighted.

An alternative to FAAS, particularly suited to the determination of metals with higher sensitivity, is electrothermal AAS (ET-AAS), in which a graphite furnace substitutes the flame as the atomization source. Generally speaking, the detection limits obtained with a graphite furnace are two orders of magnitude lower than those reached with flame atomization.

Comparing ET-AAS and ICP, techniques with similar scopes in food analysis, confirms that absorption techniques require less expensive instruments and usually achieve higher sensitivities. Since ICP is a particularly fast method, a laboratory that has to analyze many metals per sample and/or many samples can justify the investment and maintenance associated with ICP.

Other intriguing spectrometric methods used in metallic species analysis, such as X-ray fluorescence spectrometry and neutron activation analysis, are unusual in food analysis.

### Electrochemical Methods

In food analysis, the most common electrochemical methods are potentiometric and voltametric.

In potentiometric methods, the potential between a reference and an indicator electrode is measured, which corresponds to the analyte activity. Because of their usefulness in food analysis, ion-selective electrodes (ISEs) that measure anions like bromide, chloride, and fluoride or cations like potassium, sodium, and calcium stand out among indicator electrodes. The characteristics and advantages of ISE include the ability to measure different anions and cations directly, the fact that they do not consume the analyte, the fact that analyses are independent of sample volume when taking direct measurements, and that moreover turbidity, color, and viscosity do not affect the measurement. Potentiometric methods are also

fast, easy to use, and inexpensive. The disadvantages of ISEs include the following: they have a relatively low sensitivity, proteins or other organic solutes can interfere in the determination, and some ions can act like ligands or can poison the electrodes.

Voltametric techniques are based on the relation between current and voltage in an electrochemical process. Among them, anodic stripping voltammetry permits metallic species determination with detection limits of parts per billion or lower. The equipment used with these techniques is much more inexpensive than that used with spectroscopic techniques that are also used in trace analysis.

Table 5 summarizes some of the electroanalytical methods usually employed in mineral analysis of foods.

### Separation Methods: Electrophoretic and Chromatographic Methods

For multielemental analysis of foods, separation methods are also used, although less frequently. Capillary electrophoresis is used to separate metallic cations like sodium, potassium, calcium, manganese, and magnesium. Among chromatographic methods, determination of anionic and cationic species using ionic chromatography, with or without the use of an ionic suppressor, and conductimetric detection should be highlighted. Table 5 reviews some separation methods applicable to the determination of minerals.

The AOAC publishes reference methods for the analysis of minerals in foods. Table 7 summarizes some of the AOAC official methods of analysis applicable to minerals.

### Analytical Quality Assurance

Quality control is of the utmost importance in the case of mineral analyses because of the low concentrations of the elements normally found in foods and the ubiquitous presence of significant levels of many of them in the environment. In addition to the standard techniques of working in a clean laboratory to reduce the potential for accidental contamination to a minimum, it is essential that procedures be validated and results checked against appropriate certified reference materials (CRMs). CRMs for most of the trace and other minerals of interest in foods are available from international reference centers such as the Community Bureau of Reference of the European Union, the National Institute of Standards and Technology of the United States, and the International Atomic Energy Agency in Vienna.

**Table 7** Official AOAC analysis methods applicable to the determination of minerals in foods

<i>AOAC method</i>	<i>Mineral</i>	<i>Food</i>	<i>Chemical reaction</i>

### Introduction

According to the globally adopted definition of the Food and Agriculture Organization (FAO) of the United Nations (UN), ‘pesticide means any substance or mixture of substances intended for preventing, destroying, attracting, repelling or controlling any pest including unwanted species of plants or animals during the production, storage, transport, distribution and processing of food, agricultural commodities, or animal feeds or which may be administered to animals for the control of ectoparasites. The term includes substances intended for use as a plant growth regulator, defoliant, desiccant, fruit thinning agent, or sprouting inhibitor and substances applied to crops either before or after transport’. Pesticides can be divided into several groups based on their specific biological effect on target pest species. Table 1 presents major chemical classes of the most important groups of pesticides, insecticides, fungicides, and herbicides, which are used against insects, fungi, and weeds (and other plants that grow where they are not wanted), respectively.

Although intended to control pests and weeds, pesticides can also be toxic to nontarget organisms, including humans. Real and perceived concerns about the impact of pesticides on human health and the environment have led to strict regulation of both their application and residue levels in food and water supplies. Maximum residue limits of pesticides in food commodities and drinking water are commonly set by national regulatory authorities and international bodies, such as the Codex Alimentarius. For regulatory purposes, pesticide residue definitions include the parent compound and any specified derivatives such as degradation and conversion products, metabolites, and impurities considered to be of toxicological significance.

Suitable (reliable and cost-effective) analytical methods are needed mostly in order to enforce pesticide residue regulations, to provide toxicological risk assessment data, and to study pesticide fate in the food chains and the environment.

### Analytical Strategies and Trends in Pesticide Residue Analysis

In a large majority of cases, multiresidue methods (MRMs), capable of simultaneously determining

more than one residue in a single analysis, usually provide the most efficient approach to pesticide residue analysis. The reasons for their application include: (1) the need for analysis of a large (and continuously increasing) number of pesticides that should be determined together with their toxicologically important metabolites/degradation products; (2) usually unknown ‘history’ of the analyzed sample, i.e., unavailable information on the field treatment and/or postharvest application of pesticides, as well as, on the character of contamination in the locality of the sample origin; and (3) economic aspects (costs, time, and labor). A possible drawback of MRMs represents a potential worsening of some parameters such as accuracy (both trueness and precision), sensitivity (limit of detection, LOD), selectivity, and ruggedness for some individual analytes. Any MRM must be carefully optimized to provide results that meet specific (fit-to-purpose) requirements for each individual analyte, thus often compromising between the analytical scope of the method and the quality of the results for all analytes.

In practice, MRMs consist of sample preparation followed by determination of residues. The sample preparation step usually involves (1) sample homogenization, (2) isolation of residues from a representative sample (extraction), and (3) separation of residues from coextracted matrix components that interfere in the determinative step (clean-up). The determinative step comprises analyte identification and quantification, which is ideally carried out by a confirmatory technique (elucidating analyte structure), otherwise a confirmation step should follow.

Gas chromatography (GC) is traditionally a prevailing determinative technique employed in multiresidue pesticide analysis. The increasing availability of GC in combination with mass spectrometry (MS) leads to continuous replacement of GC with conventional detectors by GC–MS for simultaneous quantitative and confirmatory analysis covering a wider range of analytes. However, many pesticide residues are not directly amenable for GC and their permanently increasing number reflects a trend in pesticide product development, i.e., transition from the use of persistent and less polar compounds to more readily degradable, more (sometimes very) polar, low volatile, and/or thermolabile pesticides. Determination of these ‘modern’ pesticides and their metabolites has been rather difficult until recent advances in liquid chromatography–mass

**Table 1** Major chemical classes of insecticides, fungicides, and herbicides

<i>Pesticide group</i>	<i>Chemical class</i>	<i>Representatives</i>
Insecticides	Carbamate	Aldicarb, carbaryl, carbofuran, fenoxycarb, methiocarb, methomyl, oxamyl, pirimicarb
	Organochlorine	Chlordane, DDT, dicofol, endosulfan, endrin, heptachlor, lindane, methoxychlor
	Organophosphorus	Acephate, azinphos-methyl, chlorpyrifos, diazinon, dimethoate, malathion, parathion, phosmet
	Neonicotinoid	Acetamiprid, imidacloprid, thiamethoxam, clothianidin, dinotefuran, nitenpyram
	Pyrethroid	Allethrin, bifenthrin, cyfluthrin, cyhalothrin, cypermethrin, deltamethrin, fenvalerate
Fungicides	Chlorine-substituted aromatics	Chlorothalonil, dicloran, quintozone (PCNB), tecnazene (TCNB)
	Dithiocarbamate	Ferbam, mancozeb, maneb, metiram, propineb, thiram, zineb, ziram
	Dicarboximide	Chlozolinate, iprodione, procymidone, vinclozolin
	Imidazole	Benomyl, carbendazim, imazalil, prochloraz, thiabendazole, thiophanate-methyl
	<i>N</i> -trihalomethylthio	Captan, captan, folpet, dichlofluanid, tolylfluanid
Herbicides	Triazole	Bitertanol, fenbuconazole, hexaconazole, metconazole, myclobutanil, penconazole
	Aryloxyalkanoic (chlorophenoxy) acid	2,4-D, 2,4-DB, dichlorprop, MCPA, MCPB, mecoprop, 2,4,5-T
	Aryloxyphenoxypropionate	Cyhalofop-butyl, diclofop-methyl, fenoxaprop-ethyl, fluazifop-butyl, haloxyfop-methyl
	Chloroacetamide	Acetochlor, alachlor, metazachlor, metolachlor
	Dinitroaniline	Benfluralin, dinitramine, pendimethalin, trifluralin
	Imidazolinone	Imazamox, imazapyr, imazaquin, imazethapyr
	Quaternary ammonium	Diquat, paraquat
	Phenylurea	Chlorotoluron, diuron, fenuron, isoproturon, linuron, metoxuron, monolinuron, neburon
	Sulfonylurea	Chlorimuron-ethyl, chlorsulfuron, metsulfuron-methyl, sulfometuron-methyl, triasulfuron
	Thiocarbamate	Butylate, cycloate, EPTC, molinate, pebulate, thiobencarb, tri-allate, vernolate
	Triazine	Ametryn, atrazine, cyanazine, prometryn, propazine, simazine, terbutryn
	Uracil	Bromacil, lenacil, terbacil

spectrometry (LC–MS) brought this powerful technique to routine laboratories and opened the door to direct, selective, and sensitive multiresidue analysis of these analytes.

Ideally, all existing pesticide residues would be analyzed by a single method; however, no current method is capable of that. Even if we neglect a much smaller group of inorganic pesticides that require different analytical methodology, the major group of organic pesticides still represents compounds of rather diverse physicochemical properties, mainly in terms of polarity, volatility, and stability (to pH, temperature, etc.) that make the ideal ‘all residue’ method impossible in practice. Based on the chemical diversity of analytes, MRMs can be further divided into (1) ‘multiclass’ MRMs (MMRMs) and (2) ‘single class’ or ‘selective’ MRMs (SMRMs), involving multiple residues from different pesticide classes or only chemically related pesticides (from

one class), respectively. Most of the SMRMs that include derivatization of specific analytes to enhance their detection sensitivity and selectivity in LC (e.g., postcolumn derivatization of *N*-methylcarbamates for fluorescence detection) or volatility and stability (and also sensitivity) for GC analysis (e.g., methylation or pentafluorobenzoylation of chlorophenoxy acid herbicides, pentafluorobenzoylation of carbendazim) are being replaced by MMRM(s) employing LC–MS in the determinative step. However, some special procedures, such as conversion of dithiocarbamates to carbon disulfide for head-space GC analysis, are still conveniently used in current practice. In some cases, the determinative step may be based on a multiclass concept, but some of the parts of the sample preparation step may be selective and vice versa. This article reviews the main sample preparation and determinative techniques applicable in analysis of pesticide residues in food matrices with

a particular emphasis on the multiclass, multiresidue strategy.

## Sample Preparation

### Sample Types

The selection of sample preparation methodology is highly dependent on both analyte and sample (matrix) characteristics. To approach the matrices in the same cost-effective ('multi') way as analytes, food, commodities, and in relation to that also sample preparation methods, are primarily classified based on the fat content; the limit between 'fatty' and 'nonfatty' food matrices being usually set at 2%.

Nonfatty foods of plant origin represent the most frequently analyzed samples for pesticide residues. Among this group, special attention is paid to fruits and vegetables that are mostly consumed raw or after minimum postharvest processing, thus potentially containing the highest residue levels and posing the highest risk to consumers. Furthermore, fruits and vegetables represent the main ingredients in products intended for infants and small children ('baby food') in which pesticide residues are especially strictly regulated and monitored (e.g., pesticide residues in baby food should not exceed 0.010 mg per kg in most European countries).

In the case of fatty foods, the analysis is commonly aimed at lipophilic pesticides, such as organochlorines (OC), that accumulate in lipidic tissues and may be persistent, posing a great risk to both consumers and the environment.

### Sample Homogenization

The analytical sample is generally a part (subsample) of a larger amount of material that arrives to a laboratory as a result of a sample collection procedure. Thorough homogenization of the original laboratory sample is necessary for obtaining a representative subsample of as low as practicable size (mostly less than 50 g). Samples should be comminuted at low temperatures reducing the risk of analyte losses via degradation or evaporation. Furthermore, milling/grinding of frozen samples at extremely low temperatures, i.e., cryogenic milling in the presence of dry ice (solid carbon dioxide) or cooled by liquid nitrogen, results in fine, highly homogeneous powder that can be easily subsampled.

### Extraction

Table 2 provides a brief overview of extraction techniques applicable to isolation of pesticide residues from food samples. Currently, classical solvent extraction (at room temperature and normal pressure)

represents the most popular extraction approach due to its simplicity, relatively low costs (mainly of investment), wide applicability to both solid and liquid food samples, and, when applied properly, a low risk of analyte losses due to degradation, evaporation, and/or irreversible adsorption. Most current MMRMs employ acetonitrile, ethyl acetate, acetone, or methanol for efficient isolation of a wide range of pesticide residues from nonfatty samples. Acidic or basic analytes may require pH adjustment. In special instances, such as isolation of quaternary ammonium herbicides (diquat, paraquat), a hydrolytic extraction using concentrated acids is applied to break strong matrix-analyte interactions. Ultrasonic extraction (USE) can facilitate extraction of analytes with less strong, yet still relatively high affinity to the matrix. Sonication is also a simple and convenient approach; however, losses of more volatile and less thermally stable pesticide residues may occur due to the increased extraction temperature.

In the case of fatty samples, the target analytes usually accumulate in fat and their selective isolation from lipidic compounds is not feasible due to the similar solubility in the extraction solvent. Thus, the analytical strategy usually involves initial isolation of fat from the matrix using less polar solvents (e.g., hexane or hexane-acetone mixture) followed by clean-up step(s) separating analytes from the lipidic fraction. Soxhlet extraction (SOX) represents a traditional, reference method for isolation of fat from various food samples. SOX is more efficient than a blending procedure; therefore, it can also be used in applications that require enhanced extraction power for overcoming analyte-matrix interactions. The major drawback of this method is its long time consumption (up to 24–48 h), which is the main reason for replacing SOX by more rapid techniques in most modern laboratories. Less time- and also solvent-consuming alternatives to SOX (and also to USE) mainly include (1) microwave-assisted (solvent) extraction (MAE or MASE) and (2) pressurized liquid (or solvent) extraction (PLE or PSE), which is often referred by its commercial name: accelerated solvent extraction (ASE<sup>TM</sup>). Nevertheless, like SOX and other procedures performed at elevated temperatures, the application of these techniques is limited to relatively stable analytes.

In PLE, the increased pressure (up to 20 MPa) helps to keep extraction solvents in a liquid state at temperatures above their atmospheric boiling points, taking advantage of their enhanced solvation power and lower viscosities and hence higher diffusion coefficients. Based on a similar principle, supercritical fluid extraction (SFE) employs even more penetrative and solvating supercritical fluids. CO<sub>2</sub> is most

**Table 2** Extraction techniques applicable in the analysis of pesticide residues in foods

<i>Extraction technique</i>	<i>Basic principle</i>	<i>Materials/chemicals and devices</i>
Classical solvent extraction	Blending (mixing, shaking) with a solvent at room temperature and normal pressure	Organic solvent(s); blenders, probes, shakers, or manual shaking
SOX	Continuous extraction at elevated temperatures with repeatedly redistilled (fresh) solvent	Organic solvent(s); dispersant, drying agent, or sorbent permeable extraction vessel (thimble) Soxhlet apparatus
USE	Blending with a solvent in the presence of ultrasound waves	Organic solvent(s); ultrasonic bath or probe
MAE	Blending with a solvent heated by microwave energy	Organic solvent(s); special extraction containers – a special microwave oven
PLE	A combination of static and dynamic (flow-through) solvent extraction at a higher pressure and usually also elevated temperatures	Organic solvent(s); dispersant, drying agent, or sorbent Special extraction vessel PLE system
SFE	A combination of static and dynamic extraction using supercritical fluids	Supercritical fluid, modifiers dispersant, drying agent, or sorbent special extraction vessel SFE system
SPE	Adsorption of analytes from liquid samples (solutions) on a sorbent followed by selective elution of analytes using suitable solvent(s)	Sorbent (usually in a cartridge or disk); solvents for conditioning, washing, and elution special device for the flow control (vacuum manifold, automatic SPE system)
SPME	Adsorption of analytes from liquid samples (solutions) on a coated fiber followed by their desorption in the GC or LC injection ports	Fused-silica fiber coated with a sorbent
SBSE	Adsorption of analytes from liquid samples (solutions) on a coated stir bar followed by their thermal desorption for GC analysis	Glass-linked magnetic stir bar coated with a sorbent thermodesorption unit
MSPD	Dispersion of a sample with a sorbent, packing of this mix in a column followed by a selective elution of analytes	Sorbent empty column/cartridge elution solvent(s)

commonly used as a supercritical fluid in SFE mainly due to its suitably low critical point (31.2°C and 7.4 MPa), safety, relatively low cost, and presence in a gaseous state at normal conditions. The first feature may offer mild extraction conditions for less stable analytes and the latter one enables an easy removal of the extraction medium (by reducing the pressure), thus a convenient concentration of analytes prior to the determinative step. Compared to the techniques employing liquid extraction solvents, SFE allows a higher degree of selectivity through better control of physicochemical properties of the supercritical fluid. In MMRMs, however, increased extraction selectivity may turn into a disadvantage, limiting the range of pesticide residues that can be isolated under the same conditions. This and other limitations, including high investment and operating costs, a relatively small sample size, and demanding method optimization, precluded a widespread implementation of SFE in pesticide residue analysis and other applications.

Extraction of pesticide residues from liquid samples can be performed using a solid sorbent material. Currently available sorbent extraction techniques include: (1) solid-phase extraction (SPE), (2) solid-phase microextraction (SPME), and (3) stir-bar sorptive extraction (SBSE). In the case of solid samples, a liquid extraction of pesticide residues (transfer into a solution) usually precedes the sorption step; thus, it should be considered rather as a clean-up than an extraction. Matrix solid-phase dispersion (MSPD) represents a unique SPE approach that combines extraction and clean-up of solid or semisolid food samples in one step. In MSPD, the sample is mixed with a sorbent (Florisil, C<sub>18</sub>, C<sub>8</sub>) that serves as a solid support in sample disruption and dispersion. The resulting mix is packed into a column from which the analytes are eluted while separated matrix components are retained by the sorbent. The main drawbacks of this approach comprise rather small sample sizes (~0.5 g) and a relatively high consumption of expensive sorbents.

SPE dominates in extraction of pesticides from water samples and it represents presumably the most flexible technique for clean-up of food extracts. SPME and SBSE use a fused-silica fiber or a stir bar, respectively, coated by a sorptive material (usually polydimethylsiloxane, PDMS, or its modifications) for partition (i.e., not complete isolation) of analytes. These techniques are convenient and fast; however, their application in quantitative MMRMs for analysis of pesticides in complex food samples is rather limited. The main disadvantages relate to strong matrix effects (matrix-dependent partition of analytes and deterioration of the coating by irreversible adsorbed matrix components), insufficiently wide polarity range to extract diverse pesticide residues, and variability of method sensitivity for different analytes depending on their partition coefficients.

### Cleanup

A highly selective extraction isolating only the analytes from the sample is hardly feasible in practice,

especially in MMRMs. Thus, food sample extracts contain various matrix components posing serious difficulties (generally called 'matrix effects') in the determinative step. The cleanup step aims to remove matrix coextractives without impairing analyte recoveries. Similarly, a thorough cleanup is not feasible in MMRMs; however, some cleanup is generally better than none because it improves method accuracy, ruggedness, and potentially decreases LODs. Table 3 gives an overview of basic cleanup techniques used for separation of pesticide residues from coextracted food components. The widely applicable approaches in MMRMs include: (1) liquid-liquid partitioning (LLP), (2) gel permeation chromatography (GPC), and (3) SPE. Stable analytes, mainly OC pesticides, can tolerate applications of more aggressive procedures, such as sweep co-distillation (SCD) or chemical (degradative) cleanup, principally serving for removal of fat from final extracts.

LLP represents a cost-effective and easy approach utilized in many MMRMs despite its imperfections including mainly the use of large volumes of

**Table 3** Basic clean-up techniques used for separation of pesticide residues from coextracted food components

<i>Clean-up technique</i>	<i>Basic principle</i>	<i>Separated matrix components</i>
LLP	Separation of compounds based on their diverse solubility in immiscible solvent layers	Compounds more polar than pesticides that separate from pesticides in the organic phase to the aqueous layer; e.g., removal of sugars and some other polar coextractives together with water from acetone and acetonitrile extracts by LLP induced by addition of nonpolar solvent, such as dichloromethane, or salts (potential loss of more polar pesticides) Compounds less polar than pesticides that separate from pesticides in a more polar layer to a less polar one; e.g., removal of lipids from acetonitrile extracts by LLP with hexane (loss of lipophilic pesticides) Ionic compounds from neutral pesticides or neutral compounds from ionic pesticides by pH adjustment in the aqueous layer
GPC	Separation of molecules by their size	Compounds larger than pesticides, mainly pigments and lipids (usually removal of low-volatile components prior to the GC analysis)
SPE	Separation of compounds based on their diverse sorption power on/affinity to the used sorbent(s)	Compounds with high affinity from pesticides with no or lower affinity to the sorbent = chemical filtration or selective elution of analytes Compounds with no or lower affinity from pesticides with higher affinity to the sorbent = separation of matrix components during sorption or washing steps
SCD	Separation of compounds based on their diverse volatility	Compounds less volatile than pesticides that undergo thermal cracking while pesticides are carried to a trap by a stream of nitrogen (mainly separation of lipids from thermally stable pesticides)
Chemical treatment	Conversion of matrix components into compounds no longer soluble in the final extract or easily removable from it	Compounds (usually lipids) that undergo degradative reactions, such as mineralization by concentrated sulfuric acid or saponification by hydroxides

potentially hazardous solvents. The widely applied Luke and Specht methods (the official US Food and Drug Administration and German DFG-S19 methods, respectively), using dichloromethane or dichloromethane–petroleum ether to remove water and polar coextractives from primary acetone extracts (with certain sacrifice in recoveries of more polar pesticides), may serve as typical examples. The recently introduced QuEChERS (QuEChERS stands for Quick, Easy, Cheap, Effective, Rugged, and Safe) method avoids the use of nonpolar solvents inducing LLP by addition of  $\text{MgSO}_4$  and  $\text{NaCl}$  to acetonitrile extracts, which leads to removal of majority of water and highly polar matrix components, yet achieving high recoveries of wide range of both GC- and LC-amenable pesticides (additional SPE clean-up is performed to remove mainly sugars and fatty acids).

GPC (also known as size-exclusion chromatography, SEC) takes advantage of similar sizes of pesticide molecules for their effective, polarity-independent separation from larger matrix molecules. The reusable character of GPC columns enables easy automation and sequential runs. However, practical disadvantages include necessary periodical controls of elution patterns, the need for post-GPC sample concentration, high solvent consumption, and waste generation. Most GPC set-ups utilize ethyl acetate–cyclohexane (1:1, v/v) mobile phase in combination with styrene–divinylbenzene gels that can be either (1) soft, such as popular Bio-Beads SX-3, with high sample capacity (used mainly for removal of higher lipid contents) or (2) rigid (PL gel, etc.) enabling faster analysis and better reproducibility of elution volumes.

SPE offers a wider spectrum of clean-up options through the use of various sorbent–solvent combinations. A traditional approach (often called adsorption chromatography), employing normal-phase separation on Florisil, silica, alumina, or charcoal sorbents, effectively separates lipids and pigments from less polar pesticides (OC) that can be selectively eluted by low-polarity solvents. However, this technique is less suitable for more polar analytes that require elution by more polar eluents resulting in decreased clean-up efficiency or that may even be irreversibly retained. Similarly, adsorption of planar matrix molecules (pigments, sterols) using graphitized carbon black (GCB) sorbent is an excellent approach provided that the pesticides are not too planar.

Strong anion or cation (SAX/SCX) exchange sorbents offer highly selective clean-up in single residue/class approach to analysis of acidic or basic pesticides. Reversed-phase sorbents (e.g.,

$\text{C}_{18}$ ,  $\text{C}_8$ , and divinylbenzene polymers) are predominantly used for retention of pesticides from water samples followed by their selective elution by small solvent volumes. In food applications, another SPE approach called ‘chemical filtration’, i.e., adsorption of matrix components, such as sugars and fatty acids on aminopropyl ( $-\text{NH}_2$ ) or primary secondary amine (PSA) sorbents, while analytes remain in the extract, can be conveniently employed in cartridge or disk formats or as a novel dispersive SPE clean-up (mixing of a small amount of sorbent with the extract).

## **Determination – Identification and Quantitation**

As mentioned above, GC and LC techniques (and GC–MS and LC–MS in particular) represent the major determinative approaches used in current MMRMs. Other, much less widely applicable and applied techniques include: (1) capillary electrophoresis and capillary electrochromatography; (2) thin-layer chromatography; and (3) an array of immunoassays, such as immunosensors and enzyme-linked immunosorbent assay (ELISA). Immunoassays are, however, relatively useful for sensitive and rather rapid and inexpensive screening (followed by a confirmatory method in the case of a positive response) of selected pesticides for which ELISA kits or sensors are available.

### **Gas Chromatography**

Currently, a conventional approach to GC analysis in pesticide MMRMs employs capillary (open tubular) columns with low-bleed stationary phases mostly consisting of dimethylpolysiloxane with 5% of phenyl (other possible methyl substituents include cyanopropyl, cyanopropylphenyl or increased phenyl content up to 50%). Relatively long capillary columns (30–60 m) of 0.25–0.32 mm inner diameters (i.d.) are commonly used in routine practice, with GC analysis times usually approaching or even exceeding 1 h. However, the rising number of required analyses leads to attempts to decrease analysis time using fast (high-speed) GC techniques (mostly in combination with MS detection), thus increasing sample throughput and potentially reducing laboratory operating costs. Currently, practical approaches to fast GC–MS applicable in pesticide residue analysis employ: (1) short, microbore capillary GC columns (i.d.  $<0.2$  mm); (2) fast temperature programming; (3) low-pressure GC–MS; (4) supersonic molecular beam for MS at high carrier

gas flow rates; and (5) pressure-tunable (also called stop-flow) GC–GC.

**Sample introduction and matrix effects in gas chromatography** Table 4 lists the sample introduction (injection) techniques applied in GC pesticide residue analysis along with their positive and negative features. Injection usually represents the most crucial part (weakest link) of the GC analysis. Moreover, in real-world analysis of pesticide residues, it is the injection step that is mainly associated with adverse matrix effects, caused by the unavoidable presence of coextracted matrix components in the injected sample. Generally, matrix effects impact all steps in GC analysis (injection, separation, and detection), potentially resulting in inaccurate quantitation, decreased method ruggedness, high LODs, and/or even reporting of false positive or negative results.

During classical splitless injection, thermal degradation and/or adsorption of certain analytes may occur. When a real sample is injected, the coextracted matrix components tend to block active sites in the inlet and column (mainly free silanol groups), thus reducing losses of susceptible analytes. This phenomenon results in higher analyte signals in matrix versus matrix-free solutions, thus in an effect called ‘matrix-induced response enhancement’. As a consequence, if analyte solutions only in solvent are used for calibration standards, the concentrations of the affected analytes in sample extracts are systematically overestimated. The extent of the matrix-induced enhancement effect is related to both the chemical structure of the analyte and type of the matrix. Organophosphorus pesticides containing P=O bonds (e.g., methamidophos, acephate, omethoate, dimethoate) are particularly prone to this matrix effect. Another possible problem associated

**Table 4** GC injection techniques applied in pesticide residue analysis

<i>Injection technique</i>	<i>Advantages</i>	<i>Disadvantages</i>
Classical splitless	Easy operation Certain protection of analytical column against nonvolatile matrix components	Degradation/adsorption of susceptible analytes Matrix-induced response enhancement Small injection volumes Potential discrimination of volatile analytes due to the liner overflow
Pulsed splitless	Reduction of the residence time in the liner resulting in the decreased analyte degradation/adsorption and reduced matrix-induced response enhancement Larger injection volumes (limited by the liner size and solvent expansion volume)	Potential transfer of nonvolatile matrix components further into the column
Cold on-column	Minimum discrimination and thermodegradation	Minimum protection of the analytical column against nonvolatile matrix components – unsuitable for real-world food samples
PTV injection	Large injection volumes (limited by the injection port liquid trapping capacity – cooling efficiency, liner surface size) Reduction of thermal degradation resulting in decreased matrix-induced response enhancement Certain protection of analytical column against nonvolatile matrix components	Potential losses of volatile analytes (evaporation with the solvent) Time-consuming optimization of operating parameters (solvent trapping, solvent and analyte evaporation)
DSI/DMI <sup>a</sup>	Large injection volumes (limited by the microvial size) Effective protection of the liner and analytical column against nonvolatile matrix components resulting in minimized matrix-induced diminishment and improved ruggedness	Potential losses of volatile analytes (evaporation with the solvent) Potential discrimination of low-volatile analytes (insufficient transfer from the microvial) Careful optimization of solvent and analyte evaporation

<sup>a</sup>DSI, direct sample introduction; DMI, difficult matrix injection.

with matrix injections involves accumulation of nonvolatile matrix components in the GC system, resulting in the formation of new active sites and gradual decrease in analyte responses in both solvent and matrix solutions ('matrix-induced response diminishment effect').

In theory, the matrix-induced response enhancement effect would be overcome by eliminating of active sites or matrix components. However, both absolute GC system deactivation and thorough clean-up are virtually impossible in practice. Alternative injection techniques, such as programmed temperature vaporizing (PTV) or pulsed splitless injection, may significantly reduce the matrix-induced enhancement due to decreased thermal degradation and/or residence time in the injection port; however, they do not eliminate it. Therefore, the efficient way to avoid this problem is to compensate for it. In this respect, matrix-matched standardization is thus far the most widely used and recommended method. Unfortunately, this approach has several drawbacks including a rather time-consuming and laborious preparation of matrix-matched standards from blanks. A novel concept of 'analyte protectants' (compound additives) can offer more convenient and effective solution. Analyte protectants are compounds that strongly interact with active sites in the GC system. When added to sample extracts and matrix-free standards alike, they can induce the same response enhancement in both instances, resulting in effective equalization of the matrix-induced response enhancement effect. Thus, this approach takes advantage of response enhancement and optimizes it rather than trying to eliminate it (or merely compensate for it).

In an attempt to decrease LODs, particularly when no concentration step is conducted in sample preparation, it is desirable to use a large volume injection (LVI) technique, such as PTV in solvent vent (split) mode or direct sample introduction (DSI). DSI is a novel LVI approach, which also has a major advantage to prevent nonvolatile matrix components accumulating in the GC system, thus potentially eliminating matrix-induced response diminishment effect, reducing the maintenance, extending column life, and generally improving method ruggedness.

**Detection in gas chromatography** A traditional approach is to employ GC with element selective detectors followed by GC-MS for confirmation of the results. However, GC-MS is rapidly becoming the preferred primary tool for determination of pesticide residues in most modern MMRMs.

*Element selective detectors* Element selective detectors applicable in pesticide residue analysis include electron capture detector (ECD), electrolytic conductivity detector (ELCD), halogen-specific detector (XSD), nitrogen phosphorus detector (NPD), flame photometric detector (FPD), pulsed flame photometric detector (PFPD), sulfur chemiluminescence detector (SCD), and atomic emission detector (AED). To cover a wider range of pesticide residues, a halogen-selective detector (ECD, ELCD, XSD) in conjunction with a phosphorus- (NPD, FPD), nitrogen- (NPD), and/or sulfur-selective detector (FPD, SCD) is commonly used. A practical approach is to split the column flow to two detectors that reduces the number of injections; however, the reduced amount of analyte that reaches the detector must be considered.

The AED would represent a useful tool for the simultaneous selective detection of a number of elements occurring in pesticide molecules; however, its rather high cost and maintenance requirements virtually ruled this detector out of the routine practice. The PFPD is another detector that can be tuned to selectively detect more elements (up to two simultaneously) based on their time-delayed chemiluminescence emission versus carbon. Thus, in contrast to the FPD that can only be employed either in phosphorus or sulfur mode, the PFPD offers simultaneous detection of these (or other) two elements. However, no element selective detector, even if it detects several elements simultaneously, is confirmatory without additional information because structural isomers with the same molecular formula may exist.

*Gas chromatography-mass spectrometry* Advantages of GC-MS over traditional methods that use multiple element selective detectors include: (1) simultaneous quantitation and confirmation of detected analytes; (2) detection of a wide range of analytes independent of elemental composition; (3) possibility to spectrometrically resolve (deconvolute) coeluting peaks; and, as a consequence, (4) reduced personnel, laboratory space, and instrumentation needs, and (5) increased sample throughput. On the other hand, GC-MS instruments are still more expensive than GC instruments with element selective detectors, and sometimes, in very complex matrices, element selective detectors may permit detection of lower concentrations of residues masked by matrix interferences in GC-MS.

An ideal approach is to screen for all potential GC-amenable pesticide residues using a sensitive, rugged, and fast MS instrument in full scan mode that enables automated (1) mass spectral deconvolution, (2) identification of pesticide residues at sufficiently

**Table 5** The main (A) ionization techniques and (B) mass analyzers currently used in GC–MS analysis of pesticide residues

<i>MS techniques</i>	<i>Application strengths</i>	<i>Application limitations</i>
<i>(A) Ionization techniques</i>		
Electron impact	Controlled and reproducible fragmentation pattern Mass spectral libraries for identification of unknowns Confirmation of analyte identity (consistent ion abundance ratios) Determination of molecular structure	Difficult determination of the molecular weight (molecular ion not always present in the spectrum)
Chemical ionization	Determination of molecular weight Increased sensitivity (less fragmentation) and selectivity (reduced chemical noise) resulting in improved detectability	Reduced ability to identify/confirm (little or no fragmentation) Decreased analytical scope
<i>(B) Mass analyzers</i>		
Quadrupole	Rugged, reliable, and highly quantitative Highly compatible with existing spectral libraries Increased sensitivity in selected ion monitoring (SIM) mode Affordable	Scan mode relatively slow (max. 10–20 spectra/s) and insufficiently sensitive SIM decreases analytical scope (targeted analysis only) and requires inconvenient time-window set-ups Low mass resolution
Ion trap	Relatively sensitive full scan mode Increased detection selectivity and confirmation ability using MS <sup>n</sup> option Affordable	Quantitation problems and space charge effects Relatively slow scanning (max. 10–20 spectra/s) MS <sup>n</sup> decreases analytical scope (targeted analysis only), sensitivity, and speed and requires time-consuming optimization Low mass resolution
Time-of-flight (TOF)	No spectra skewing (optimal for deconvolution)	Reduced ruggedness Expensive (especially the high-resolution variant) Large data files
(a) High-speed TOF	Fast spectral acquisition rate (up to 500 spectra/s) for very and ultrafast GC–MS and GC × GC techniques	Lower mass resolution
(b) high-resolution TOF	High resolution (7000 FWHM at $m/z$ 614) improving detection selectivity	Relatively slow spectral acquisition rate (up to 10 spectra/s)

low concentrations using mass spectral libraries/pesticide databases, and (3) reliable quantification of detected residues. Table 5 indicates how the capabilities of the main MS (ionization and ion separation) techniques currently used in GC–MS analysis of pesticide residues approximate this ideal.

### High-Performance Liquid Chromatography

**Traditional detectors and postcolumn derivatization** Traditionally, LC served mostly for analysis of single or small groups of non-GC-amenable pesticide residues for which derivatization for GC was unsuitable or complicated. Besides a lower number of possible theoretical plates, the main reason for its inferior position as compared to GC consists in the

limited variety and capabilities of traditional LC detectors, such as ultraviolet/visible (UV/VIS), diode array (DAD), or fluorescence (FLD) detectors. Although DAD offers improved selectivity versus a single-wavelength UV/VIS detector, they are both restricted to the detection of analytes with chromophores and usually do not provide sufficiently low LODs for residue analysis in complex matrices. FLD is a substantially more selective and sensitive option; however, only few pesticides have a fluorophore in their molecular structure. In some instances, postcolumn derivatization may be performed to convert the analytes to fluorescent derivatives, such as hydrolysis of *N*-methylcarbamates to methylamine and its subsequent reaction with *o*-phthalaldehyde (and 2-mercaptoethanol).

**Liquid chromatography–mass spectrometry** The initial attempts to couple LC with MS lacked important attributes for trace analysis: sensitivity, robustness, and reliable quantitation. Moreover, the cost of the early LC–MS instruments was prohibitive for most laboratories. The revolutionary introduction of atmospheric pressure ionization (API) techniques, mainly electrospray (ESI) and atmospheric pressure chemical ionization (APCI), resulted in greater applicability of LC–MS and manufacture of more reliable, affordable, and user-friendly instruments. Thus, LC–MS is now becoming an indispensable part of the analytical strategy in many routine laboratories, enabling direct, selective, and sensitive multiclass, multiresidue analysis of more polar, low volatile, and/or thermolabile pesticides, such as carbamates, phenylureas, sulfonylureas, imidazoles, triazoles, imidazolinones, chlorophenoxy acids, and many others.

A drawback of using soft API techniques involves reduced spectral information (often only a protonated  $[M + H]^+$  or deprotonated  $[M - H]^-$  molecular ion in positive or negative ionization mode, respectively) resulting in decreased selectivity and limited confirmation ability. Thus, in most applications, the use of tandem MS, either tandem-in-time (ion trap MS<sup>n</sup>) or more expensive and reliable tandem-in-space (combination of two mass analyzers for MS–MS, such as triple quadrupole, quadrupole-TOF) instruments, becomes essential for achieving both low LODs (increased signal-to-noise ratios due to improved selectivity) and almost unambiguous confirmation. High-resolution MS may also offer greater selectivity and confidence in analyte identity; however, at substantially higher costs.

Similarly to LC with traditional detectors, LC–MS also mainly employs reverse-phase LC with modified silica stationary phases; however, the composition of mobile phases is rather limited to methanol or acetonitrile as principal organic modifiers and to volatile additives (buffers).

Matrix effects complicate not only GC but also LC–MS analysis. Matrix components may impact selective determination of coeluting analytes (a rare effect in tandem MS) and mainly interfere in the spraying, ionization, and evaporation processes leading to analyte signal suppression or less often enhancement. To compensate for the latter effects, matrix-matched standardization is mostly used after failure of more convenient approaches, such as application of a different ionization technique (APCI is usually better than ESI in this respect), altered LC separation, or improved sample preparation selectivity. In the case of a limited number of analytes, the use of deuterated internal standards or echo-peak

technique (injection of a standard solution shortly after the sample resulting in closely eluting peaks of the same analyte) represent less laborious compensation methods than matrix-matched standardization.

This article is a revision of the previous-edition article by Maurice O Moss, pp. 1490–1499, © 1995, Elsevier Ltd.

### Introduction

The mycotoxins are fairly low relative-molecular-mass secondary metabolites of filamentous fungi that are toxic to humans and domesticated animals, causing illness, or even death, when contaminated foods or animal feeds are consumed. There are many toxic metabolites produced by fungi but only a fraction of these are currently considered to be important in foods. Similarly, a very broad range of fungal species may produce toxic metabolites, but in human food the most important genera are *Aspergillus*, *Penicillium*, and *Fusarium*. Although the presence of a mycotoxin in a food usually implies the previous infection by, and growth of, the producing mold on the food, or a constituent of the food, there are two significant instances when that is not so. Mycotoxins can be passed through the food chain ending up in a commodity that was not itself moldy. Thus, aflatoxin M<sub>1</sub> is secreted into milk following consumption by a cow of feed contaminated by aflatoxin B<sub>1</sub>. Ochratoxin A can pass unmetabolized into the kidney and muscle tissue of the pig after feeding on a contaminated feed such as barley.

### Range of Mycotoxins Encountered in Foods

Major problems encountered in the analysis of mycotoxins arise because of their diversity of chemical structure and the wide range of foods and animal feeds in which some of them may occur. This often means the development of quite different analytical methods for each mycotoxin in each food

commodity. **Table 1** lists the most important mycotoxins that have been found in food. The structures of these mycotoxins are shown in **Figures 1–11**.

The diversity in chemical structure of the mycotoxins is reflected in a diversity of biosynthetic pathways and biological activity. **Table 2** provides information on the toxicity of the more important toxins. Recognition of the importance of some mycotoxins is reflected in the production of statutory and advisory regulations for maximum tolerated levels in foods and animal feeds in many countries. In the case of the aflatoxins the low levels set for maximum tolerated concentrations (**Table 3**) reflect the assumption that these compounds are carcinogenic to humans, coupled with the ability of the analyst reproducibly to detect such low levels in a wide range of foods and animal feeds. At least 50 countries have regulations in place or proposed for the control of aflatoxins in food or animal feeds, and about a one-fourths of these countries also have regulations governing permitted levels for other mycotoxins such as ochratoxin, patulin, deoxynivalenol, and zearalenone. Many countries have especially stringent levels for aflatoxin M<sub>1</sub> in milk and dairy products ranging from 0.01 µg per kg in pasteurized fresh milk for infants in Austria to 0.5 µg per kg for milk and milk products in the USA. This, in part, reflects concern for exposure of the very young and elderly, who would be more likely to be both more sensitive and have a higher level of exposure. International trade in many of the commodities most at risk from contamination requires the establishment of agreed methods of analysis and many countries use those described in the Official Methods of Analysis of the Association of Official Analytical Chemists.

### Sampling

Before an analysis can be attempted a sample must be obtained. The analyst is frequently presented with a

single sample, adequate in quantity for the analytical methodology, but without any guarantee that it is representative of the consignment of food of animal feed from which it came. Many of the commodities

to be analyzed are particulate in structure and molds do not grow uniformly through such materials. Thus, mycotoxins that are not usually distributed evenly may be aflatoxins in milk and patulin in fruit juice,

**Figure 2** Cyclopiazonic acid.

**Figure 7** Penitrem A.

**Figure 3** Deoxynivalenol (R1 = H) and nivalenol (R1 = OH).

**Figure 8** Sterigmatocystin.

**Figure 4** Fumonisin B<sub>1</sub> (R1 = OH, R2 = OH), fumonisin B<sub>2</sub> (R1 = H, R2 = OH), and fumonisin B<sub>3</sub> (R1 = OH, R2 = H).

and it is important to agree to a sampling plan that adequately protects the consumer without unnecessarily penalizing the producer. There is not even a normal distribution of mycotoxins within a batch of a commodity. For example, in the contamination of groundnuts, maize, cotton seed, or palm kernels with aflatoxin, it is likely that a relatively small number of kernels or seeds are contaminated with very high levels and many are not contaminated at all, giving a very skewed distribution.

Satisfactory sampling plans, such as those devised for groundnuts by the US Department of Agriculture (USDA) and the Tropical Products Institute (now the Natural Resources Institute) of the UK, should define the size of the sample, how it is to be collected, a method for dividing the sample, and an analytical procedure. The USDA sampling plan for the determination of aflatoxins in groundnuts requires that 66 kg of material be collected from at least 100 sacks for each 20 ton lot. The 66 kg is divided into three subsamples of 22 kg and the first of these is ground, thoroughly mixed, and analyzed. At a time when the maximum tolerated level was 25 µg per kg, if the

result of this first analysis was less than 16 µg per kg the lot was accepted, if greater than 75 µg per kg it was rejected. If, however, the first analysis gave a result between these two figures, then the second subsample had to be analyzed in the same way. If the mean of the two is less than 22 µg per kg the lot was accepted and if greater than 38 µg per kg rejected but, again, if the result fell between these two figures then the third subsample had to be analyzed. In this example, the mean of all three now needs to be less than or equal to 25 µg per kg for the lot to be accepted.

For many years sampling was not taken sufficiently seriously but detailed research on the distribution of mycotoxins in commodities and an appropriate statistical analysis of the results have led to the increased use of acceptable sampling plans. The recognition of the extremely skewed distribution of mycotoxins has also led to the design of methods for recognizing and eliminating the heavily contaminated kernels from consignments, thus ensuring that they do not contribute to the overall contamination of the batch after further treatment such as mixing, grinding, and oil extraction.

## Extraction Procedures and Cleanup

Mycotoxins are produced in a complex matrix of macromolecules, including proteins, polysaccharides, and lipids, and many of the plant commodities most at risk of contamination contain a complex range of low-relative-molecular-mass organic compounds. Although many mycotoxins are readily soluble in water-immiscible organic solvents, it is not always

**Table 2** Toxicity and biological effects of major mycotoxins

<i>Mycotoxin</i>	<i>Biological activity</i>	<i>LD<sub>50</sub> (mg per kg)</i>
Aflatoxin B <sub>1</sub>	Hepatotoxic, carcinogenic	0.5 (dog), 9.0 (mouse)
Cyclopiazonic acid	Convulsions	36 (rat)
Deoxynivalenol	Vomiting, feed refusal	70 (mouse)
Fumonisin B <sub>1</sub> , B <sub>2</sub> , B <sub>3</sub>	Equine encephalomalacia, pulmonary edema and hydrothorax in pigs, esophageal carcinoma	?
Nivalenol	Gastrointestinal disturbances, cytotoxic and immunosuppressive	4.1 (mouse)
Ochratoxin	Nephrotoxic	20–30 (rat)
Patulin	Oedema, haemorrhage, possibly carcinogenic	35 (mouse)
Penitrem A	Tremorgen	1.05 (mouse)
Sterigmatocystin	Hepatotoxic, carcinogenic	166 (rat)
T-2 and HT-2 toxins	Gastrointestinal disturbances, cytotoxic and immunosuppressive	5.2 (T-2 mouse) 9 (HT-2 mouse)
Tenuazonic acid	Convulsions, haemorrhage	81 (female mouse) 186 (male mouse)
Zearalenone	Oestrogenic	Not acutely toxic

**Table 3** Maximum acceptable levels for a range of mycotoxins in foodstuffs for a selection of countries

<i>Mycotoxin</i>	<i>Country</i>	<i>Limit (<math>\mu\text{g per kg}</math>)</i>	<i>Matrix</i>
Aflatoxin B <sub>1</sub>	EU	2	Nuts or dried fruit intended for direct human consumption or as an ingredient in foodstuffs
Aflatoxin B <sub>1</sub> , B <sub>2</sub> , G <sub>1</sub> , G <sub>2</sub>	EU	4	Nuts or dried fruit intended for direct human consumption or as an ingredient in foodstuffs
Aflatoxin B <sub>1</sub> , B <sub>2</sub> , G <sub>1</sub> , G <sub>2</sub>	Canada	20	Feeding stuffs for animals
Aflatoxin M <sub>1</sub>	EU	0.025	Infant formulae including infant milk. The maximum level for infant formulae refers to the product ready to use after reconstitution
Aflatoxin M <sub>1</sub>	US	0.5	Milk for human consumption
DON	US	5000	Grain by product not to exceed 40% of animal diet. Includes animals other than feedlot cattle older than 4 months, beef cattle older than 4 months, chickens, and swine
Fumonisin B <sub>1</sub> , B <sub>2</sub> , and B <sub>3</sub>	US	3000	Cleaned corn intended for popcorn
Ochratoxin A	EU	3	All products derived from cereals including processed cereal products and cereal grains intended for direct human consumption
Ochratoxin A	Switzerland	0.5	Processed cereal based baby foods
Ochratoxin A	Hungary	15	Green coffee
T-2 toxin	Bulgaria	100	Cereals intended for direct consumption or as an ingredient in foodstuffs

easy to remove them from the macromolecular food matrix by direct extraction with simple solvents such as chloroform or ethyl acetate. It may be necessary to remove oils and fats by a preliminary extraction with hexane before extracting the mycotoxin.

In the case of aflatoxins, detailed methods will vary from one commodity to another. Thus, defatted hazel nuts, pistachios, Brazil nuts, groundnuts, or groundnut meal, can be extracted directly with chloroform after the addition of a small volume of water, whereas cottonseed and cottonseed products are best extracted initially with aqueous acetone and the aflatoxins subsequently partitioned into chloroform. Established procedures for aflatoxins that illustrate these principles include:

(1) 'Groundnuts'. Comminuted material (50 g) is extracted with hexane in a Soxhlet extractor for 3–4 h. Residual solvent is removed from the solid in a warm oven with an appropriate extractor fan. To 10 g of defatted material, in a 250 ml stoppered flask, 10 ml of water is added and mixed thoroughly using a glass rod. Chloroform (100 ml) is added, the flask stoppered, and the mixture shaken on a wrist shaker for 30 min. The extract is filtered, a measured volume taken to dryness under a stream of nitrogen, transferred to a vial in a known volume of chloroform, and retained for subsequent analysis.

(2) 'Cottonseed meal'. Comminuted material (25 g) is extracted with 250 ml acetone–water (85:15; v/v) on

a wrist shaker for 30 min. The crude extract is filtered and 100 ml treated with 20 ml lead acetate solution (20% neutral lead acetate trihydrate in deionized water with 3 ml glacial acetic acid added per liter) and 80 ml deionized water. The mixture is stirred well and allowed to stand for 5 min before treating with filter aid (5 g) and filtering through a Whatman No. 4 filter paper. A measured volume of this filtrate (100 ml) is extracted with chloroform (50 ml) in a separating funnel. The chloroform layer is allowed to drain through a column containing a layer (2 cm) of anhydrous sodium sulfate, a layer of 5 g acidic alumina, and topped off with an additional layer (2 cm) of anhydrous sodium sulfate. The aqueous residue is extracted with a second portion of chloroform (50 ml) and the chloroform layer drained through the same column. The combined filtrate is taken to dryness under nitrogen and transferred quantitatively to a vial for subsequent analysis.

Those mycotoxins, such as ochratoxin A, which contain a carboxyl group, can be readily extracted into an organic solvent such as chloroform after acidifying the commodity to ensure that it exists entirely in the undissociated form. Aqueous phosphoric acid ( $0.1 \text{ mol l}^{-1}$ ) is frequently used. Ochratoxin A can then be back-extracted from the chloroform using sodium hydrogencarbonate solution or trapped on a column of diatomaceous earth

impregnated with a basic aqueous solution such as sodium hydrogencarbonate. Esters and fat can be removed with hexane and chloroform and the acidic ochratoxin A eluted with a formic acid–chloroform mixture.

Some mycotoxins are sufficiently hydrophilic that they cannot be recovered efficiently with a simple chloroform extraction even though they are intrinsically soluble in chloroform. Amongst the trichothecenes, deoxynivalenol is best extracted initially with aqueous methanol, before subsequently partitioning into chloroform. Indeed, the dependence on relatively nonpolar organic solvents for the convenient extraction of mycotoxins from foods, animal feeds, and raw materials may be one of the reasons why the fumonisins have only recently been isolated and characterized, despite their toxicological importance and widespread occurrence. Fumonisins are associated with encephalomalacia in horses, edema of the lung in pigs, liver carcinoma in rats, and may be responsible for esophageal carcinoma in humans. They are produced by *Fusarium moniliforme* and related species of the *Liseola* group of *Fusarium* and it is now realized that they are widespread in cereals such as maize and can occur naturally in very high concentrations. Their extraction from maize can be carried out in acetonitrile–methanol–water (25:25:50; v/v/v) by shaking for 20 min or by homogenization or blending for 5 min.

Cleanup procedures vary considerably depending on both the mycotoxin(s) and the commodity to be analyzed. For many commodities slurries of freshly precipitated iron(III) hydroxide and copper(II) carbonate have proved effective in removing co-extractives. Flocculation of impurities with aqueous lead acetate or zinc acetate has also been used. Some mycotoxins can be adsorbed onto silica gel and/or florosil and subsequently eluted. Indeed, a range of commercially available prepared columns, such as Sep-Pak, have proved very convenient as a cleanup stage for crude extracts of mycotoxins before subsequent analysis.

More recently cleanup procedures have been developed purposely for mycotoxins. The principle of immunoaffinity, where an antibody specific to a particular mycotoxin is immobilized onto an inert solid support and packed into a column, is most commonly used. Such a column can be used to absorb a mycotoxin from a known volume of a food extract or liquid with very little, if any, preliminary cleanup. Most of the constituents of the extract pass through the column or can be washed off the column with water. Because the mycotoxins are not covalently bound to the column they can be displaced with an organic solvent such as methanol. This produces a

very clean, concentrated extract that is then usually analyzed by liquid chromatography (LC), gas chromatography (GC), or directly by fluorimetry for those mycotoxins that fluoresce. A major disadvantage of this technique is the cost of the columns as they can only be used once because the antibodies are destroyed when releasing the mycotoxins. Immunoaffinity columns are commercially available for total aflatoxins (B<sub>1</sub>, B<sub>2</sub>, G<sub>1</sub>, G<sub>2</sub>), aflatoxin B<sub>1</sub>, aflatoxin M<sub>1</sub>, ochratoxin A, deoxynivalenol, fumonisin B<sub>1</sub>, B<sub>2</sub>, and B<sub>3</sub>, T-2 toxin, zearalenone, and total aflatoxins and ochratoxin A together in one column.

There is also a range of cleanup columns for mycotoxins that allow rapid one-step purification with no washing or eluting. The sample extract is passed through a packing material consisting of charcoal, alumina, and silica where the impurities are retained whilst the mycotoxins pass through the packing material with a cleaner solution. As the packing material is impregnated with impurities each column can only be used once. These columns will cleanup extracts for single mycotoxins or ones with similar properties including fumonisins, ochratoxin A, moniliformin, and trichothecenes. Others exist for purification of samples for a range of mycotoxins, for example, one column for aflatoxins, zearalenone, and patulin.

The recovery of mycotoxins from all extraction and cleanup procedures needs to be validated and this is usually done using carefully spiked material prepared from clean samples of the commodity under study. It must, however, be recognized that it is usually easier to recover compounds from spiked samples than it is to recover the same mycotoxins from naturally contaminated material, and for some mycotoxins there are available samples of naturally contaminated material the mycotoxin content of which has been established by international collaborative studies. The extraction and cleanup procedures will still usually provide a complex mixture requiring further separation before a specific physicochemical method for the quantitative or qualitative analysis of individual mycotoxins can be applied. This further separation is usually carried out by some form of chromatography.

## Chromatographic Methods

The separatory power of a wide range of chromatographic methods can be used as a final cleanup stage before determination of a specific mycotoxin, with thin-layer chromatography (TLC), in either one- or two-dimensional mode, LC, and GC being the most common.

### Thin-Layer Chromatography

All the aflatoxins fluoresce intensely under long-wave UV (360 nm) when absorbed on a solid substrate such as the silica gel of a TLC plate (this is not always true in solution). Thus, TLC proved to be especially useful during the early days in the study of the etiological agents of turkey X disease leading to the recognition, isolation, and characterization of the aflatoxins. Indeed, the two groups of aflatoxins, B and G, are so labeled because of the bluish or greenish fluorescence that they produce.

The problem with the simple TLC analysis of aflatoxins is that many natural products fluoresce blue or green under UV and many of these compounds have an  $R_F$  value close to, or even identical with, that of one of the four common aflatoxins (Figure 1). The early literature contains a number of false-positive reports of the presence of aflatoxins, and even their production by species of mold other than *Aspergillus flavus*, *A. parasiticus*, and *A. nomius*, so it is essential that a confirmatory test be carried out such as derivatization coupled with two-dimensional TLC. In the case of the aflatoxins, a useful confirmatory test is to derivatize as the hemiacetals with trifluoroacetic acid by superimposing 2  $\mu$ l of a 50% solution of the reagent in chloroform onto the spot of both the unknown and a standard marker before chromatography. Aflatoxins B<sub>1</sub> and G<sub>1</sub>, but not B<sub>2</sub> and G<sub>2</sub>, form hemiacetals that have the same fluorescence as the parent compound but run significantly more slowly

in the commonly used solvent systems. The fluorescence of all four aflatoxins, and the derivatives of B<sub>1</sub> and G<sub>1</sub>, change from blue or green to yellow after spraying the plate with 25% aqueous solutions of an inorganic acid such as sulfuric or nitric acids.

Table 4 lists a selection of TLC methods used for some of the more important mycotoxins listed in Table 1.

### Liquid Chromatography

Although many well-validated methods existed for TLC-based analysis of several mycotoxins, once the equipment became readily available LC has frequently been the technique of choice for quantitative determination. A major advantage of LC is the possibility of automation and the use of autosamplers allowing the unattended operation of LC equipment. Online clean-up of crude extracts and online derivatization before or after separation are additional advantages. A range of detectors can be used, although the most widespread are based on UV absorption or the detection of fluorescence, the latter being potentially 30–40 times more sensitive for aflatoxins. Although the four common aflatoxins fluoresce well in the solid state on TLC plates, the fluorescence of aflatoxins B<sub>1</sub> and G<sub>1</sub> is weak in many solvents. This can be overcome in a number of ways. The aflatoxins can be converted to hemiacetal derivatives with trifluoroacetic acid before chromatography occurs. Postcolumn treatment with iodine-saturated water, or more commonly pyridinium bromide perbromide solution, is increasingly becoming

**Table 4** TLC methods for some mycotoxins

Mycotoxin	Solvent (v/v)	Detection method	Detection limit ( $\mu$ g per kg)
Aflatoxins	Acetone–CHCl <sub>3</sub> (1:9)	Fluorescence under UV (360 nm)	1–5
Aflatoxin M <sub>1</sub>	CHCl <sub>3</sub> –acetone–2-PrOH (87:10:3)	Fluorescence under UV (360 nm)	0.05
Cyclopiazonic acid	EtOAc–2-PrOH–NH <sub>3</sub> aq (50:15:10)	<i>p</i> -Dimethylaminobenzaldehyde spray (blue fluorescence)	125
Deoxynivalenol	CHCl <sub>3</sub> –2-PrOH–acetone (8:1:1)	AlCl <sub>3</sub> spray, heat 7 min, 120°C, blue fluorescence	40
Ochratoxin A	Benzene–acetic acid–MeOH (90:5:5)	Exposure to NH <sub>3</sub> –MeOH vapor, blue fluorescence (360 nm)	10
Patulin	Toluene–EtOAc–CHCl <sub>3</sub> –formic acid (105:45:48:3)	MBTH <sup>a</sup> spray, heat 5 min, 130°C, yellow brown fluorescence (360 nm)	120–130
Penitrem A	CHCl <sub>3</sub> –acetone (93:7)	Spray 1% FeCl <sub>3</sub> in BuOH gentle warming, purple blue color	–
Sterigmatocystin	Benzene–acetic acid–MeOH (90:5:5)	AlCl <sub>3</sub> spray, heat 5 min, 110°C, yellow–green fluorescence (360 nm)	5–10
Tenuazonic acid	Benzene–acetic acid–MeOH (90:5:5)	Fluorescence quenching on Hf <sub>254</sub> plates (250 nm)	2 $\mu$ g per spot
Zearalenone	CHCl <sub>3</sub> –MeOH (97:3)	Blue fluorescence under UV (25 nm)	10

<sup>a</sup>MBTH, 3-methyl-2-benzothiazolinone hydrazine hydrochloride (0.5 g in 100 ml water).

the method of choice. Postcolumn derivatization can also be afforded by addition of potassium bromide and nitric acid to the mobile phase, which is passed through an electrochemical (Kobra) cell to produce the bromine derivatizing agent. The change in intensity of the peaks with and without postcolumn treatment is a useful confirmation of the presence of aflatoxin B<sub>1</sub> and G<sub>1</sub>.

The electrochemical detector has been used for the analysis of roquefortine and the zearalenones and refractive index detection has been used for trichothecenes such as T-2 toxin with no native fluorescence or useful UV absorption. For molecules such as T-2 toxin, with a free hydroxyl group, it is possible to derivatize with a reagent such as an aromatic acid, which confers UV absorption on the derivative.

There are well-established methods for the LC analysis of all the aflatoxins, ochratoxin A, zearalenone and its metabolites, the 8-keto trichothecenes, patulin, and the fumonisins. The fumonisin method uses precolumn derivatization with *o*-phthaldialdehyde and mercaptoethanol, despite the limited stability of the resulting compounds. Naphthalene-2,3-dicarboxaldehyde/potassium cyanide has been proposed as a viable alternative, although handling requires additional safety precautions.

### LC-MS (MS/MS)

The use of a mass spectrometer as a detector for LC analysis brings a number of benefits to mycotoxin analysis. There is no need for chromophores or fluorophores in the analytes so derivatization can be avoided. The chemical structure of the analytes can be confirmed from molecular mass and fragmentation information and the use of tandem MS (MS/MS) allows greater selectivity. Multiple reaction monitoring and selected ion monitoring modes mean that chromatographic separation of all analytes is not necessary, as differentiation is carried out by the different ion transitions measured, and many multiresidue mycotoxin LC-MS methods now exist. These data acquisition modes can also increase the sensitivity of the method as the background noise is often reduced.

Methods exist for many matrix/mycotoxin combinations including patulin in apple juice using atmospheric pressure photoionization, zearalenone and its metabolites in fish tissue and porcine urine, muscle, and liver tissues using electrospray ionization, trichothecenes (T-2 toxin, HT-2 toxin, acetyl T-2 toxin, diacetoxyscirpenol, neosolaniol, and monoacetoxyscirpenol) in grain using atmospheric pressure chemical ionization, and trichothecenes (T-2 toxin, HT-2 toxin, deoxynivalenol, nivalenol), zearalenone and its metabolites ( $\alpha$ - and  $\beta$ -zearalenol and  $\alpha$ - and  $\beta$ -zearalanol) in eggs.

### Gas Chromatography

For GC the mycotoxins need to be sufficiently thermostable and volatile to be converted into volatile derivatives. The most widely used detectors in mycotoxin GC analysis are flame ionization (FID), electron capture (ECD), and mass spectrometry (MS). These do not require that a compound show any fluorescence or UV absorption and the groups of mycotoxins for which GC is the most suited are the trichothecenes and the fumonisins.

Many mycotoxins, including the trichothecenes and fumonisins, have polar hydroxyl groups that can be readily derivatized to trimethylsilyl ethers with such reagents as trimethylsilyl chloride or hexamethyldisilazane and *N*-trimethylsilylimidazole. Alternatively, polyhalogenated acyl derivatives can be made, using reagents such as trifluoroacetic anhydride or heptafluorobutyric anhydride, which are especially useful in conjunction with the ECD.

There are a large number of different trichothecenes and ideally their analysis requires confirmation using GC-MS and analysis of the macrocyclic trichothecenes, which includes the verrucarins, roridins, and satratoxins, requires considerable experience and a specialized laboratory. However, well-established methods are available for individual trichothecenes of particular importance, such as T-2 toxin, diacetoxyscirpenol, deoxynivalenol, and neosolaniol. The large number of *Fusarium* trichothecenes are acylated derivatives of a much smaller number of parent alcohols, such as T-2 tetraol, scirpentriol, deoxynivalenol, and nivalenol, so another approach to their analysis is to hydrolyze the possibly complex mixture of trichothecenes to the parent alcohols and analyze these as their trimethylsilyl ethers. However, when this is done, there is often a poor correlation between total trichothecene content and observed toxicity, reflecting the large differences in the toxicity of different acyl derivatives even of the same parent alcohol.

Methods for the GC analysis of the fumonisins require the hydrolytic removal of the two very polar tricarboxylic acid residues and subsequent trimethylsilylation of the several hydroxyl groups and amino acid groups present in the parent molecule. Ideally confirmation with GC-MS is still desirable but only available in a very limited number of laboratories.

### Immunological Methods

Modern LC and GC apparatus in conjunction with automated sample cleanup allow multiple samples to be analyzed in one run, increasing the throughput of

analyses greatly. Immunological approaches to mycotoxin determination can also be used if a large number of analyses are required. Although mycotoxins are relatively small molecules, and hence not themselves immunologically active, they can form the haptens of an antigen by coupling to a suitable macromolecule such as bovine serum albumin. They may then present suitable epitopes to which specific antibodies can be raised.

During the last few years immunological methods have been developed for a wide range of mycotoxins including the aflatoxins, T-2 toxin, zearalenone, ochratoxin, cyclopiazonic acid, and, most recently, fumonisins B<sub>1</sub>, B<sub>2</sub>, and B<sub>3</sub>.

The manner in which the mycotoxin is linked to the macromolecular carrier can have a profound effect on the activity and specificity of any antibody raised, especially if it is monoclonal. Ochratoxin already has a carboxyl group that can be used directly to form a derivative with a carrier but many mycotoxins need to be linked to the carrier via a reactive linker molecule. Different linking molecules may be attached to different sites of a polyfunctional mycotoxin, thus exposing different parts of the molecule as potential epitopes. Aflatoxin B<sub>1</sub> can be derivatized through oxime formation on the pentenone ring leaving the difuran ring system exposed, or through the hemiacetal on the difuran ring leaving the  $\delta$ -lactone/pentenone ring system exposed (Figure 12). In the first case the antibody would be expected to distinguish between the unsaturated aflatoxins

(B<sub>1</sub> and G<sub>1</sub>) and their dihydrocompounds (B<sub>2</sub> and G<sub>2</sub>). In the second case the antibody would be expected to distinguish the B group from the G group.

The specificity of monoclonal antibodies make it possible to develop an analytical method for a single mycotoxin, such as aflatoxin B<sub>1</sub> in maize and groundnut meal, or aflatoxin M<sub>1</sub> in milk and milk products. Even within chemically closely related structures such as the *Fusarium* trichothecenes there is very little cross-reactivity between a monoclonal raised to a single toxin such as T-2 toxin and other members of the family. Thus, a monoclonal raised against 3-acetyl-deoxynivalenol showed negligible cross-reactivity with deoxynivalenol, nivalenol, or T-2 toxin.

### Enzyme-Linked Immunosorbent Assay

Enzyme-linked immunosorbent assay (ELISA) methods are widely used in medical and food analysis laboratories and it seems appropriate that such methods could be used for the detection of mycotoxins in foods. In the direct ELISA method the antibody is bound to a solid surface, such as a microtiter plate, and it is necessary to prepare a conjugate of the mycotoxin to be analyzed with the enzyme, such as phosphatase or peroxidase, to be used for color development. The sample or standard is mixed with the enzyme-linked mycotoxin and the two allowed to compete for the antibody bound to the surface. After washing away soluble material, the

**Figure 12** The possibility of forming two distinct antibodies to aflatoxins.

quantity of enzyme bound to the antibody, which is inversely proportional to the concentration of mycotoxin in the original sample, is determined by adding the chromogenic reagent.

Although the indirect competitive ELISA seems to be more complex it is in fact more widely used, an advantage being the stability of the mycotoxin conjugate prepared using a protein such as keyhole limpet hemocyanin, or a synthetic polypeptide such as polylysine, compared with the mycotoxin enzyme conjugate required for the direct assay. The conjugate is used to coat the surface of the assay system that might be a microtiter plate for a quantitative assay carried out in a laboratory or a preprinted plastic card for a qualitative assay suitable for application in the field. These coated surfaces are stable and can be stored for long periods of time. In the indirect method the surface-coated mycotoxin conjugate is incubated with a mixture of the sample and the specific rabbit antibody. Once soluble material has been washed away any bound antibody (which will again be inversely proportional to the concentration of mycotoxin in the original sample) is visualized with a goat antirabbit IgG enzyme complex, several of which are readily available commercially, and subsequent color development. Commercial ELISA analytical kits are available for most mycotoxins including total aflatoxins, aflatoxin B<sub>1</sub> aflatoxin M<sub>1</sub>, ochratoxin A, citrinin, zearalenone, T-2 toxin, deoxynivalenol, fumonisins, patulin, and moniliformin, and AOAC standard procedures exist.

## Biological and Biochemical Assays

Before confidence was gained in the specificity and sensitivity of physicochemical methods of analysis the acceptable assay for the presence of aflatoxins in foods and animal feeds was a biological assay using 1-day-old ducklings in which test samples were injected into the gizzard via a plastic tube. The acute LD<sub>50</sub> doses for 1-day-old ducklings have been estimated to be (mg per kg) B<sub>1</sub>, 0.36; B<sub>2</sub>, 1.69; G<sub>1</sub>, 0.78; G<sub>2</sub>, 2.45. Physicochemical and immunological methods have replaced this type of bioassay for individual mycotoxins but they also can only be applied to the analysis of known mycotoxins. If the question is more general, and there is a need to assess the presence of mycotoxins, some of which may be of unknown structure, in a sample, then a bioassay may be needed. An appropriate bioassay may alert the analyst to the presence of unknown toxic metabolites, or of synergistic interactions between several toxic metabolites in a mixture. The most

widely used bioassays involve crustacea such as brine shrimp larvae, protozoa such as *Tetrahymena*, or a range of tissue cultures of mammalian origin. Such methods are not specific and may give false-positive results because of the sensitivity of the test organism to a normal food component. Thus, brine shrimp larvae are sensitive to long-chain fatty acids.

Cytotoxicity tests, using a range of tissue cultures, would seem to provide a system more closely related to the whole animal. Baby hamster kidney cells, and human cells lines such as HE<sub>p</sub>-11, which are especially sensitive to trichothecenes, and Chang liver cells, have been successfully used for screening for the presence of toxic metabolites in food extracts.

An interesting biochemical assay has been developed for ochratoxin A, which can be split into ochratoxin  $\alpha$  and phenylalanine by the enzyme carboxypeptidase A with a loss of fluorescence intensity at 380 nm. It is a sensitive assay and has been adapted for the analysis of ochratoxin A in blood samples and seta.

## Standard Procedures

The following accepted methods, which have been evaluated and validated through collaborative studies, are extensively described by Scott, for the AOAC, who also provides detailed information on the apparatus, reagents, the preparation of standards, and sampling:

- 968.22: Aflatoxins in peanuts and peanut products – CB method
- 970.45: Aflatoxins in peanuts and peanut products – BF method
- 970.46: Aflatoxins in green coffee – TLC method
- 971.23: Aflatoxins in cocoa beans – modification of CB method
- 971.24: Aflatoxins in coconut, copra, and copra meal – TLC method
- 972.26: Aflatoxins in corn – TLC method
- 974.16: Aflatoxins in pistachio nuts – TLC method
- 975.36: Aflatoxins in foods and feeds – Romer minicolumn method
- 972.27: Aflatoxins in soy beans – TLC method
- 979.18: Aflatoxin in corn and peanuts – Holaday-Velasco minicolumn method
- 973.37: Ochratoxins in barley – TLC method
- 973.38: Sterigmatocystin in barley and wheat – TLC method
- 974.17: Aflatoxin M<sub>1</sub> in dairy products – TLC method
- 974.18: Patulin in apple juice – TLC method

- 975.38: Ochratoxin A in green coffee – TLC method
- 976.22: Zearalenone in corn – TLC method
- 978.15: Aflatoxin B<sub>1</sub> in eggs – TLC method
- 980.21: Aflatoxin M<sub>1</sub> in milk and cheese – TLC method
- 980.20: Aflatoxins in cottonseed products – TLC and liquid chromatography methods
- 982.24: Aflatoxins B<sub>1</sub> and M<sub>1</sub> in liver – TLC method
- 982.25: Aflatoxins B<sub>1</sub> and M<sub>1</sub> in liver – confirmation method
- 982.26: Aflatoxin M<sub>1</sub> in liver – confirmation method
- 985.17: Identification of aflatoxin B<sub>1</sub> – confirmation method
- 985.18:  $\alpha$ -Zearalenol and zearalenone in corn – liquid chromatography method
- 986.16: Aflatoxins M<sub>1</sub> and M<sub>2</sub> in fluid milk – liquid chromatography method
- 986.17: Deoxynivalenol in wheat – TLC method
- 986.18: Deoxynivalenol in wheat – GC method
- 989.06: Aflatoxin B<sub>1</sub> in cottonseed products and mixed feed – ELISA screening method
- 990.33: Aflatoxins in corn and peanut butter – liquid chromatography method
- 990.34: Aflatoxin B<sub>1</sub>, B<sub>2</sub>, and G<sub>1</sub> in corn, cottonseed, peanuts, and peanut butter – ELISA method
- 991.31: Aflatoxins in corn, raw peanuts, and peanut butter – immunoaffinity column (Aflatest) method
- 991.44: Ochratoxin A in corn and barley – liquid chromatography method
- 991.45: Total aflatoxin levels in peanut butter – ELISA method
- 993.16: Total aflatoxins (B<sub>1</sub>, B<sub>2</sub>, and G<sub>1</sub>) in corn – ELISA method
- 993.17: Aflatoxins in corn and peanuts – TLC method

## Safety Procedures

Mycotoxins should be handled as toxic substances and special care should be taken when handling pure toxins in a dry form, or samples (including TLC plates), which may be a source of dust. Accidental spillages of material containing toxin can generally be treated with 1% sodium hypochlorite bleach, left for 10 min, and swabbed down with 5% aqueous acetone initially and subsequently with plenty of water.

Glassware exposed to aflatoxins can be rinsed with methanol soaked in 1% sodium hypochlorite

solution to which, after 2 h, acetone is added to 5% of the total volume. The acetone is left for 30 min to destroy any potentially harmful but reactive intermediates formed by hypochlorite and then washed thoroughly. It is known, for example, that aflatoxin B<sub>1</sub> can form a carcinogenic derivative if treated with hypochlorite alone.

A very detailed discussion of the laboratory decontamination and destruction of aflatoxins in laboratory wastes has been prepared for the International Agency for Research on Cancer.

## Soft Drinks

**J Sadecka and J Polonsky**, Slovak University of Technology, Bratislava, Slovakia

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

There are many kinds of soft drinks (fruit and vegetable juices, fruit and vegetable nectars, and water-based flavored drinks including 'sport' or 'electrolyte' drinks) that are formulated with different recipes and not all the ingredients are found in all soft drink products. Typically, the ingredients include water, sugars, sweeteners, preservatives, antioxidants, colorants, flavors, and pH adjusters. Ingredient contents of major types of soft drinks are given in Table 1. Most regular (nondiet) soft drinks contain ~90% of water from a pure source, while diet soft drinks contain up to 99% of water. Regular soft drinks are sweetened with cane or beet sugar, high fructose corn syrups, or blends of these sweeteners. These sugars result in a mixture of sucrose and/or fructose and glucose in the final product. Most diet soft drinks are sweetened with aspartame. The ingredients that are used in soft drinks are approved and closely regulated by the US Food and Drug Administration (FDA) and the national laws and regulations. The main additives allowed in soft drinks are listed in Table 2.

The soft drink samples are analyzed in order to monitor the quality of products, determine the contaminants, or verify the authenticity of products.

### Quality

#### Sugars

Global sugar content is obtained by indirect refractometry ('Brix') or Fourier transform infrared spectroscopy (FTIR). Although sugars are nonultraviolet (UV) absorbing molecules, the UV/UV method allows the simple determination of the global sugar content. Under the influence of UV radiation sugars are oxidized (in buffer, pH 9.0) to UV-absorbing carbonyl compounds. The formation of these compounds is monitored by UV absorption spectrometry at the wavelength of maximum absorbance of 268 nm.

Individual sugars are estimated using thin-layer chromatography (TLC) and high-performance liquid chromatography (HPLC). The main advantage of TLC is that it is rapid and inexpensive; its disadvantage is that it only provides semiquantitative information on all of the principal sugars typically encountered in drinks, e.g., monosaccharides, fructose, glucose and the disaccharides, sucrose, maltose, and lactose and also higher oligosaccharides consisting of 3–10 monosaccharides. These preliminary results are then confirmed using other techniques, e.g., enzymatic.

The most commonly used analytical technique for sugars is HPLC with a refractive index detector (RID). Although the HPLC–RID method is simple, the RID lacks sensitivity and selectivity. Therefore, UV and fluorescence detection is frequently used, coupled with pre- or postcolumn derivatization, for analysis with higher sensitivity. Liquid chromatography–mass spectrometry (LC–MS) using electrospray ionization also requires pre- or postcolumn derivatization. LC–MS using atmospheric pressure chemical ionization does

**Table 1** Ingredient content of major types of soft drinks

Flavor type	Total sugars ( $\text{g l}^{-1}$ )	Phosphorous ( $\text{mg l}^{-1}$ )	Caffeine ( $\text{mg l}^{-1}$ )	Aspartame ( $\text{mg l}^{-1}$ )	Acid (%)

GMP limited by Good Manufacturing Practices.

not require pre- or postcolumn derivatization; however, this method requires  $\text{CHCl}_3$  and  $\text{CH}_2\text{Cl}_2$  to be added in the postcolumn stage. As an alternative technique, HPLC with pulsed amperometric detection is used for nonderivatized sugars.

Nonderivatized sugars including mono- and disaccharides, aminosugars, and sugar alcohols can be determined by capillary zone electrophoresis (CE) with indirect UV detection. CE is not yet in use in routine analysis. However, the method's simplicity and stability make it suitable for the application in routine labs.

### Artificial Sweeteners

Beverages that are popular as diet soft drinks are made using low-calorie artificial sweeteners such as

saccharin, aspartame, acesulfame-K, and cyclamate. Many methods are used for analyzing individual sweeteners (titration, photometric, fluorimetric, and enzymatic), but relatively few methods are capable of simultaneously analyzing several sweeteners.

HPLC with reversed-phase (RP) or ion-pair RPLC and UV detection is the most popular choice for the determination of aspartame, saccharin, and acesulfame-K. However, the lack of a chromophore in the cyclamate molecule makes its determination difficult using the common HPLC–UV detection mode. A high-performance anion-exchange chromatographic method with UV and conductivity detectors connected in series offers an attractive alternative for simultaneous determination of the four sweeteners and also citric acid.

### Preservatives

The use of benzoic and sorbic acids as preservatives is widespread. Although both acids are highly efficient against yeasts, molds, and to a lesser extent against bacteria, sorbic acid has the advantage of being active in less acidic media (unlike pH values of 6) and in addition has no taste. HPLC including reversed-phase, ion-exclusion, and ion-exchange chromatography is the most common analytical procedure for the determination of these acids.

### Antioxidants

Antioxidants are usually classified into two groups: natural (e.g., ascorbic acid, flavonoids, tocopherols) and synthetic.

HPLC with UV-based diode array detection (DAD–UV) or electrochemical detection is normally used to determine ascorbic acid. Many types of electrochemical determinations of ascorbic acid have been proposed. Although the electrochemical determinations using enzyme-based biosensors exhibited high specificity and sensitivity, these methods suffer in the fabrication of the electrodes and in automatic analysis. Recently, chemically modified screen-printed electrodes have been constructed for the determination of ascorbic acid. This is one of the most promising routes for mass production of inexpensive, reproducible, and reliable electrochemical sensors.

The analyses of flavonoids are usually carried out by HPLC with UV or DAD–UV detection. Since flavonoids are found as complex mixtures, hyphenated techniques are needed. Among those, LC–MS represents a rapid and reliable technique.

### Colorants

The colorants permitted for use in drinks can be divided in two categories: synthetic (azo or

triarylmethane dyes) and natural (anthocyanins or caramel).

Today, synthetic colorants have largely replaced natural colorants and there are laws that strictly control their use. The maximum amounts allowed and the acceptable daily intakes have been decreased. As these values differ for various colorants, it appears necessary to identify and quantify the colorants present in drinks.

Usually, only two or three colorants are added. Due to this reason and taking into account the economic feasibility and rapidity, double division-ratio spectra derivative, inverse least-squares, and principal component regression methods are reliable for the simultaneous determination of the colorants in the drinks without a priority procedure such as separation, extraction, and preconcentration.

The chromatographic methods are applied when the sample contains many different colorants. RPLC and ion-pair RPLC with DAD or MS detection are the most widely used methods. Both isocratic and gradient systems are used and the latter is preferred for the separation of more complex mixtures. Although some samples can be injected directly, for most LC methods colorants must be extracted first from the matrices and purified as well as concentrated prior to chromatography. All the pretreatment techniques are time consuming and sometimes expensive, making them unsuitable for routine analysis. High-performance ion chromatography on an anion-exchange column with very low hydrophobicity proved to be a promising method for the separation of colorants. No time-consuming pretreatment, as used in conventional chromatography, is needed.

Anthocyanins are responsible for the blue, red, and purple colors of fruits. The anthocyanin profiles of some products derived from red fruits are used to verify the authenticity of these products. RPLC is the most common method for the separation of anthocyanins.  $C_{18}$  columns are commonly used for the separation and single wavelength detectors can selectively monitor anthocyanins between 520 and 546 nm, where no other plant phenolics show absorption. The separation is accomplished more effectively with gradient elution using methanol or acetonitrile as an organic modifier. The pH of the gradient system is normally kept below two. Anthocyanins can also be separated by micellar electrokinetic chromatography (MEKC). The MEKC analysis requires lesser time not only for separation, but also for reconditioning the capillary.

The caramels used in soft drinks are classified as Class IV caramels. The established method for determination of caramels is a simple spectrometric measurement at 610 nm. This method cannot distinguish

between caramel classes or between caramel and other compounds that absorb at 610 nm. CE at acidic pH can discriminate between Class I, III, and IV caramels. A reliable, robust method for the analysis of Class IV caramels by CE has recently been developed.

### Aroma and Flavor

Natural aroma and flavors in soft drinks come from spices, natural extracts, and oil. There are also some artificial flavorings (quinine, caffeine, naringenin, and hesperidin).

Aroma and flavor compounds usually occur at low concentrations and consist of a wide range of organic compounds. Most aroma and flavor compounds are volatile and procedures for isolation from samples such as steam distillation, solvent extraction, and trapping of the volatiles on adsorbent require a long time prior to chromatographic separation. The volatile compounds are also analyzed using either direct headspace or dynamic headspace purge-and-trap methods. The headspace solid-phase microextraction (SPME) in combination with gas chromatography (GC) or GC-MS can be used for the analysis of various juices. The SPME methods coupled with HPLC or LC-MS are used for the analysis of less volatile or thermally labile compounds. These techniques provide accurate measurements and define the right chemical nature of the aroma compounds. However, they are complicated and expensive, unsuitable for real-time, online, and *in situ* sensing.

Sensorial analyses based on the sensor arrays and pattern recognition algorithms seem to be very promising in encountering the mentioned advantages. Various kinds of gas sensors are available, but only metal oxide semiconductors and conducting organic polymers are used in commercialized electronic noses. The electronic nose can only perform quick 'yes' or 'no' test to compare products. Therefore, it cannot totally replace either the human nose or other analytical methods.

Following the development of the electronic nose for gas analysis, the electronic tongue (an array of potentiometric chemical sensors) has been devised for the analysis of complex liquid samples. If properly configured and trained (calibrated), the electronic tongue is capable of recognizing the qualitative and quantitative composition of multicomponent solutions of different natures. The electronic tongue and electronic nose, in combination, can be used to predict the sensory characteristics and their relationship to the quality of, e.g., apple juices measured by a trained sensory panel and consumers.

Quinine is a flavoring agent used in soft drinks. Several methods are available for the determination

of quinine (UV-vis spectrometry, fluorimetry, ion-selective electrode) but these methods are generally not very selective. There are certain drawbacks to the spectrophotometric methods such as strong influence from benzoic acid and the presence of coloring materials. The same problems will be expected when the fluorimetric method is applied. The use of ion-selective electrode is advantageous over the spectral methods because no interference from those species is expected. Chromatographic techniques, especially LC, are widely used with quinine detection by means of its fluorescence or UV absorption.

In some cases, small amount of caffeine is added to soft drinks. Caffeine has a classic bitter taste that enhances other flavors. UV spectrometry, HPLC, and CE are used for the determination of caffeine in beverages. All of the above methods require sample preparation. FTIR spectroscopy with chemometrics, using partial least squares first derivative spectrum in the region between 2800 and 3000  $\text{cm}^{-1}$ , have been developed to directly determine the caffeine in soft drinks.

Naringenin and hesperidin are examples of bittering compounds used in soft drinks. RPLC with UV-DAD is the method of choice for the analysis of naringenin and hesperidin.

## Acids

Acids are used in soft drink to balance the sweeteners and to inhibit the growth of microorganisms such as yeasts, molds, and bacteria. Soft drinks are acidified either by the addition of fruit juices or by the inclusion of an acid. The three most commonly used acids are citric, malic, and phosphoric. Other acids such as tartaric and fumaric are also used. Citric acid is found in citrus fruits, blackcurrants, strawberries, and raspberries. Malic acid is found in apples, cherries, plums, and peaches. Phosphoric acid is generally used in cola drinks.

Titrimetry is routinely used to determine total titratable acids (results are expressed as gram anhydrous citric acid per kilogram).

HPLC and enzymatic methods are used for the determination of citric and malic acids in routine analysis. Tartaric, fumaric, and phosphoric acids are normally determined by HPLC. The choice of a given HPLC method depends on the nature of acids and sample matrix. The most general method is ion-exclusion chromatography followed by RP chromatography because these two methods provide better, faster, and more reliable data compared to ion-exchange and ion-pair RPLC. The better-shape peaks are obtained employing ion-exclusion

chromatography, and faster analysis times are achieved using RPLC.

## Carbon Dioxide

Carbon dioxide is an essential characterizing ingredient in all 'carbonated' beverages. It can be measured volumetrically, manometrically, or automatically using a thermal conductivity detector.

A new method for the determination of dissolved  $\text{CO}_2$  in beverages is based on passing the liquid over the retentate side of a membrane that is at least partially permeable to the gas, measurement of the volumetric flow of the gas to the permeate side, measurement of liquid temperature, and calculation of the gas concentration using these data. Carbonate can also be determined using online coupling of gas diffusion to a CE system.

## Miscellaneous

HPLC is used increasingly in the analysis of soft drink samples to separate and detect natural compounds and additives. Differences in the respective molecular characteristics of this range of compounds would make the simultaneous separation of these compounds by HPLC quite difficult although ion-pair RP or ion-exchange methods could be used (Table 3). The high separation capabilities of CE, and ease with which the running buffer and/or the micellar phase can be modified, suggests it may be suitable for complex determinations (Table 4). However, both these methods do not allow easy, continuous monitoring, because they are 'slow'. Biosensors offer advantages as alternative to conventional methods due to their specificity, simplicity, and quick response.

## Contaminants

### Microbial Spoilage

Soft drinks have high water activity ( $a_w$ ) that permits microbial growth. Combinations of hurdles, such as pH and chemical preservatives, prevent the growth of most microorganisms. A variety of microorganisms may be found in soft drinks; however, only a few acid-tolerant spoilage organisms are of significance. Molds grow only when dissolved oxygen is present, as may be the situation in certain noncarbonated drinks. Acid-tolerant bacteria grow well at a soft drink pH level. Since yeasts can tolerate extreme conditions better than bacteria, they are often found in acidic products and products containing preservatives to such an extent that bacteria cannot grow. Especially, yeast spoiling has increased in recent years as a result of lower doses of preservatives

**Table 3** Simultaneous separations by HPLC methods

<i>Compounds</i>	<i>Column type</i>	<i>Mobile phase</i>	<i>Detection</i>
Inorganic anions and carboxylic acids	Ion-exchange	Sodium hydroxide gradient in water–methanol–ethanol	Suppressed conductivity
Sugars, ascorbic acid, and furanic compounds	Ion-exchange	Aqueous sulfuric acid, acetonitrile	RI and diode-array UV
Carboxylic acids, sugars, glycerol, and ethanol	Ion-exchange	Aqueous sulfuric acid	RI
Organic acids and phenolic compounds	Reversed phase	Methanol gradient in sulfuric acid	Diode-array UV
Antioxidants, benzoic and sorbic acids, and sweeteners	Reversed phase	$\alpha$ -Hydroxyisobutyric acid, hexadecyltrimethylammonium bromid, acetonitrile	UV

RI, refractive index.

**Table 4** Simultaneous separations by CE methods

<i>Compounds</i>	<i>Method</i>	<i>Electrolyte</i>	<i>Detection</i>
Inorganic ions, organic acids, amino acids, and carbohydrates	CE	2,4-Pyridine dicarboxylic acid, cetyltrimethylammonium hydroxide, pH 12.1	Indirect UV
Antioxidants, benzoic and sorbic acids, and sweeteners	MEKC	Borate, sodium cholate, sodium dodecyl sulfate, methanol, pH 9.3	Direct UV
Colorants, preservatives, and sweeteners	MEKC	Carbonate, sodium dodecyl sulfate, pH 9.5	Direct UV–vis

CE, capillary zone electrophoresis; MEKC, micellar electrokinetic chromatography.

required for high standards of food quality. The most known alternatives are characterized by abundant gas production, cloudiness, sediment and off-flavor formation, and off-tastes.

The analytical methods used by the industry to evaluate yeasts present in drinks are still, generally, laborious and provide poor information. The most common microbial indicator is still the ‘yeasts and molds’, resulting from the utilization of a rich culture medium (supplemented with antibiotics to prevent bacterial growth) to enumerate yeasts and molds. However, this indicator does not distinguish between the dangerous spoilage yeasts and others.

Several methods have been developed for the differentiation of yeasts. Traditional plating techniques may be adapted using selective and/or differential plating media. Such media have been developed for *Zygosaccharomyces bailii*, the most important of all food spoilage yeasts. However, yeast differentiation by differential media is poorly developed when compared with similar works applied to bacteria. Other phenotyping methods include conventional yeast identification by means of assimilation or fermentation tests and the use of morphological characteristics. Conventional methods are not suited to industrial laboratories even when these procedures are automated and computerized.

Another approach concerns the use of biomarkers, such as the composition of cellular molecules like fatty acids and nucleic acids (DNA and RNA). Fatty acid composition has been used successfully in differentiating the most important yeasts. A gas chromatograph is required to implement this technique. Based on the presence or absence of polyunsaturated C18 fatty acids it is possible to separate yeasts in groups of three levels. The most dangerous yeasts for fruit concentrates and juice industry are in group III. The yeasts of group I may be dangerous to the fruit concentrates, fruit juices, and soft drinks industry. The yeasts of group II are considered as dangerous. The difficulty for the food industry is the absence of a database of long-chain fatty acid profiles for the main food contaminant yeasts. From a technological point of view, fatty acid profiling of yeasts is more easily applicable than nucleic acid methods. Fatty acid profiles would give the probable identification of a given yeast strain, which could be confirmed using a molecular primer of the species expected to have been found.

### **Mycotoxins**

Mycotoxins are highly toxic compounds produced by fungi. Thus, in fruit juices several mycotoxins

have been identified: alternariol is produced by *Alternaria alternata* in apple, cranberry, grape, and raspberry juice. *Byssoschlamys nivea* in grape, pineapple, apple, orange, and tomato juices produced by ochlamic acid. Citrinin is produced by *Penicillium expansum* in apple and grape juices. Ochratoxin A is produced by *Aspergillus carbonarius* in grape juices. Patulin is produced by *Byssoschlamys fulva*, *Byssoschlamys nivea*, and *Penicillium expansum* in fruit juices.

Currently most mycotoxins are still assayed using TLC, which permits effective compound separation and characterization. When the compounds to be detected are fluorescent, a fluorodensitometry reads the plates quantitatively and objectively. However, the use of RPLC has expanded rapidly in recent years. The diversity of detection systems (DAD, fluorescence, and MS) permits identification and accurate assay of a great variety of these compounds. Recently, a database for 474 mycotoxins and fungal metabolites for dereplication by standardized LC–UV–MS has been reported. Sample preparation techniques include: extraction of mycotoxins using mostly chloroform, acetone, or methanol, purification of the extract with cleanup methods, and concentration of the extract.

Alternariol can be determined using gradient RPLC with UV detection at 254 nm, although fluorescence or MS detection have also been used. Sample preparation involves extraction with dichloromethane and purification of the extract by silica column chromatography using diethyl ether–hexane in the washing step and ethyl acetate–methanol for elution of analyte. Besides, cleanup of the sample can be carried out in two steps using first a polypropylene C<sub>18</sub> SPE column, followed by aminopropyl SPE column.

The usual methods for the assessment of ochratoxin A are immunochemical detection or RPLC coupled with fluorescence detection ( $\lambda_{\text{ex}} = 247 \text{ nm}$ ,  $\lambda_{\text{em}} = 480 \text{ nm}$ ). For ochratoxin sample preparation, the sample is mixed with HCl and MgCl<sub>2</sub>, followed by extraction into toluene. The toluene supernatant is passed through a silica gel column and the column is washed with hexane, toluene–acetone, and toluene. Ochratoxin A is eluted with toluene–acetic acid and dried down to 40°C. The residue is dissolved in a mobile phase, filtered, and analyzed by HPLC. The limit of ochratoxin A in grape juice is proposed to be fixed at 3 µg per kg.

The patulin level can be determined using gradient RPLC with UV detection (270 nm). For patulin sample preparation, two procedures are described: (1) juice sample can be cleaned on an Extralut cartridge followed by patulin extraction on a silica gel column

with toluene–ethyl acetate; (2) patulin can be extracted into ethyl acetate followed by extraction of phenolic acids into carbonate solution. Next, the carbonate layer is back-extracted with ethyl acetate. After evaporation of the combined ethyl acetate layers, the residue is dissolved in methanol–ethyl acetate and it is to be analyzed by RPLC. Researchers recommended that apple juice should not contain residual patulin level in excess of 50 µg l<sup>-1</sup>.

Detection of mycotoxins usually requires a time- and solvent-consuming sample preparation step. A new, simple procedure based on diphasic dialysis extraction coupled with GC–MS has been demonstrated to be effective in reducing solvent consumption for the determination of patulin in apple juices. Using a semipermeable membrane, patulin was extracted from an apple juice sample into a methane chloride organic phase. An improvement in *in situ* derivatization and higher extraction recoveries have been obtained by means of the addition of 4-*N,N*-dimethylaminopyridine as derivatization activator and acetic anhydride as derivatizing agent to the sample and to the dialyzing solvent, respectively.

### Anionic Toxins

A rapid determination of anionic toxins (cyanide, arsenite, arsenate, selenate, and azide) in beverages is possible using CE. These toxins can be detected within 15 min, requiring only minimal sample pretreatment. Compared to ion chromatography, the advantages of CE are the shorter analysis time, the minimal sample pretreatment, and the simultaneous analysis of azide and arsenate together with cyanide and arsenite.

### Residues of Pesticides

In most countries, growing concern about the residue of pesticides in beverages is evident. Regulations limiting the concentrations of pesticides have been introduced. Several methods are used to control these limits. TLC or bioanalytical techniques involving inhibition of enzyme reactions, bioassays using fungal spores, or immunological techniques may be used as an initial screening to detect whether a residue is present before a sample is subjected to a more complex instrumentation analysis (GC–MS or HPLC).

### Authenticity

Adulteration of fruit juices and concentrates is a problem that has received wide publicity. Common methods of adulteration either alone or in combination include addition of water, corn syrup, cane and beet invert sugar, peel extract, pulp wash, cheaper

**Table 5** Authenticity methods for juice

<i>Method</i>	<i>Provision</i>	<i>Adulteration</i>
IRMS	Carbon stable isotope ratio of sugars	Addition of corn syrup or cane sugar to most juice with the exception of pineapple
IRMS	Oxygen stable isotope ratio in fruit juice water	The fraudulent sale of juice made from concentrated as freshly squeezed
IRMS/NMR	Combination of five isotope ratio	Addition of beet sugar
Pyrolysis-MS	Pectin	Addition of pulp wash and/or peel extract
Liquid chromatography	Ratio hesperidin/narirutin, summary flavonoid glycoside and hesperidin	Addition of pulp wash to orange juice
Liquid chromatography	Organic acids profile, minor acids, citric/isocitric acid ratio	Addition of cheaper juice, e.g., grapefruit added to orange juice can be detected by tartaric acid
Liquid chromatography/enzymatic	Sugar profile of sucrose, glucose and fructose or amino acids, e.g., D-malic acid	Addition of cane and beet invert sugar, addition of D,L-malic acid

MS, mass spectrometry; NMR, nuclear magnetic resonance.

juices, colorants, and other undeclared additives, often to mimic the composition profiles of pure juices. Because of the diversity in adulteration techniques, a variety of test methods may be necessary (Table 5). Multiple-component chemical analyses are required to reliably evaluate the differences between adulterated and pure juice. This approach, however, is both time consuming and expensive. Near-infrared spectroscopy seems to be a very useful tool to reduce the cost of authenticity checking. In the case of a good database, near-infrared spectroscopy could be proposed as a rapid preliminary screening method to find the out-layers differing from the other authentic samples. Out-layers only have to be analyzed using the more expensive and time-consuming analytical procedure.

Carbon stable isotope ratio (CSIR) analysis of sugar utilizing an isotope ratio mass spectrometer (IRMS) is routinely used to detect the addition of cane sugar and corn syrup to most juices with the exception of pineapple. The inability of CSIR analysis to detect beet sugar in orange and apple juices because of metabolic similarities between adulterant and authentic products has required alternative methods, e.g., combination of IRMS and nuclear magnetic resonance (NMR) spectroscopy. The method requires the determination of five isotope ratios after fermentation of the juice: the  $^2\text{H}/^1\text{H}$  and  $^{18}\text{O}/^{16}\text{O}$  ratios of the fermentation water plus the total  $^{13}\text{C}/^{12}\text{C}$  and  $^2\text{H}/^1\text{H}$  ratios on the methyl and methylenic groups of the alcoholic distillate.

Flavonoid glycosides provide an excellent fingerprint for juices that are not subjected to extensive pretreatment to remove them. There are a large number of these compounds in citrus juice. Hesperidin and narirutin are typical of sweet orange, whereas naringin and neohesperidin can be used to

**Table 6** Hesperidin/narirutin ratios and naringin/neohesperidin ratios in citrus juices

<i>Citrus juice</i>	<i>Hesperidin/ narirutin ratio</i>	<i>Naringin/ neohesperidin ratio</i>
Orange	4–12	–
Orange pulp wash	2.5–3.9	–
Murcott	0.3–0.5	–
Tangerine	2–3	–
Lemon	> 7	–
Grapefruit	< 0.1	15–80
Pommerans	> 4	1
Bergamot	> 4	1.5

identify grapefruit (Table 6). The ratio hesperidin/narirutin (H/N) in pulp wash differs from that of orange juice and if this ratio is low, ranging from 2.5 to 3.9, the orange juice can contain pulp wash. For increasing amounts of murcott juice, or grapefruit juice in orange juice, narirutin increases, resulting in a lower H/N ratio. Blending with grapefruit, pommeranse, or bergamot juices may clearly be proved by the presence of naringin and neohesperidin. On the basis of the naringin concentrations, it even may be possible to trace the addition of very low percentages (<2%) of these juices in orange juice.

Fruit juices each have very distinct organic acid profiles that can be used as fingerprint for establishing authenticity. HPLC methods that compare ratios of the major acid components are limited in most cases because the adulterators can add synthetic acids so that the ratios are consistent with those found in pure juice. Some minor acids analysis is a more powerful technique, since it is not economically feasible to adjust the levels of all acids, many of which are expensive. D-isocitric acid in lower

**Table 7** The content of D-isocitric acid and citric acid/D-isocitric acid ratio in different fruit juices

Fruit juice	D-isocitric acid content (mg l <sup>-1</sup> )	Citric acid/D-isocitric acid ratio
Orange	65–200	80–130
Grapefruit	140–350	50–90
Lemon	240–420	170–260
Mandarin	70–90	120–140
Raspberries	60–220	80–200
Apricot	70–200	15–150

concentrations can be found in various fruits (Table 7). The determination of D-isocitric acid is important especially in the evaluation of citrus juices. Simple falsification of orange concentrate or juice by addition of sugars, citric acid, and water can be detected from the citric acid/D-isocitric acid ratio, which is usually lower than 130 in authentic orange juice.

## Introduction

The beverages coffee, cocoa, and tea can be considered complex mixtures of naturally occurring substances (for example, methylxanthine alkaloids, flavonoids, organic acids, pigments, and nutritional elements) and compounds generated during industrial processes, such as roasting, fermentation, and decaffeination. This article will provide a brief overview of the major chemical components commonly encountered in coffee, cocoa, and tea, together with the standard procedures for the extraction and analyses of these major components.

## Survey of Major Analytes

The major analytes of coffee include caffeine, chlorogenic acids, and flavor and volatile aromatic components. The major analytes in cocoa are methylxanthines, mainly theobromine and trace amounts of caffeine, cocoa fat, and lipids. Other analytes of interest in cocoa are tannins, pigments, and aroma components. The major analytes of tea are the methylxanthine alkaloids, including caffeine and theophylline, polyphenols (catechins, tannins, and related flavanols), and volatile and aromatic components. Analysis of black tea would also include theaflavins and thearubigens, which are oxidation and condensation products of polyphenols.

## Sample Preparation and Extraction Techniques

### Sample Preparation

Green coffee beans are ground to pass a No. 40 sieve before extraction and analysis. Roasted coffee beans

**Table 7** The content of D-isocitric acid and citric acid/D-isocitric acid ratio in different fruit juices

Fruit juice	D-isocitric acid content (mg l <sup>-1</sup> )	Citric acid/D-isocitric acid ratio
Orange	65–200	80–130
Grapefruit	140–350	50–90
Lemon	240–420	170–260
Mandarin	70–90	120–140
Raspberries	60–220	80–200
Apricot	70–200	15–150

concentrations can be found in various fruits (Table 7). The determination of D-isocitric acid is important especially in the evaluation of citrus juices. Simple falsification of orange concentrate or juice by addition of sugars, citric acid, and water can be detected from the citric acid/D-isocitric acid ratio, which is usually lower than 130 in authentic orange juice.

## Introduction

The beverages coffee, cocoa, and tea can be considered complex mixtures of naturally occurring substances (for example, methylxanthine alkaloids, flavonoids, organic acids, pigments, and nutritional elements) and compounds generated during industrial processes, such as roasting, fermentation, and decaffeination. This article will provide a brief overview of the major chemical components commonly encountered in coffee, cocoa, and tea, together with the standard procedures for the extraction and analyses of these major components.

## Survey of Major Analytes

The major analytes of coffee include caffeine, chlorogenic acids, and flavor and volatile aromatic components. The major analytes in cocoa are methylxanthines, mainly theobromine and trace amounts of caffeine, cocoa fat, and lipids. Other analytes of interest in cocoa are tannins, pigments, and aroma components. The major analytes of tea are the methylxanthine alkaloids, including caffeine and theophylline, polyphenols (catechins, tannins, and related flavanols), and volatile and aromatic components. Analysis of black tea would also include theaflavins and thearubigins, which are oxidation and condensation products of polyphenols.

## Sample Preparation and Extraction Techniques

### Sample Preparation

Green coffee beans are ground to pass a No. 40 sieve before extraction and analysis. Roasted coffee beans

and tea samples are ground to pass a No. 30 sieve before analysis. Soluble coffee solids, instant tea, and cocoa powder are analyzed after thorough mixing to ensure homogeneity. Cocoa products other than cocoa are extracted with petroleum ether to remove fat before extraction and analysis of alkaloids and other nonvolatile components.

## Extraction Techniques

### Methylxanthine alkaloids

*Caffeine in coffee and tea* The Bailey–Andrew method, the Power–Chesnut method, and the Levine method have been adopted by the Association of Official Analytical Chemists (AOAC) for the extraction and determination of caffeine in coffee and tea.

In the Bailey–Andrew method, 5–10 g of ground sample is weighed into a 1 l Erlenmeyer flask with 500 ml of water. The mixture is heated to boiling, and 10 g of magnesium oxide (MgO) is added. The mixture is boiled over low flame for a period of 2 h, water being added periodically to prevent frothing. After cooling, water is added to make to weight (1000 g) and the mixture is filtered. Twenty milliliters of sulfuric acid is added to 200 ml of clear filtrate. The acidified sample is extracted successively with 25, 20, 15, 10, 10, 10 ml portions of chloroform. Five milliliters of potassium hydroxide solution (1%) is added to the pooled chloroform extract. The remaining aqueous potassium hydroxide layer is washed with two 10 ml portions of chloroform. All chloroform portions are collected into a Kjeldahl flask. After evaporation of the chloroform, the amount of caffeine extracted is determined by measuring the total nitrogen (Kjeldahl method).

In the Power–Chesnut method, 10 g of coffee sample is transferred into a Soxhlet extractor with ethanol, and extracted with ethanol for up to 8 h. The ethanolic extract is transferred into a porcelain dish containing 10 g of high-density MgO and 100 ml of water. Ethanol in the mixture is evaporated by slow heating on a steam bath. The residue is moistened with hot water and filtered into a 1 l flask. The filtrate is acidified with 20 ml of sulfuric acid and brought to boiled for 30 min. After cooling, the acid extract is filtered into a separator. The filtrate is extracted with chloroform (six 25 ml portions). The combined chloroform extract is washed with 5 ml of 1% KOH solution. The chloroform phase is drained into an Erlenmeyer flask and the KOH portion is washed with two portions of chloroform (10 ml each). All chloroform extracts are pooled, and the volume of extract is reduced to 10 or 15 ml by distillation. The remaining chloroform extract is transferred to a weighing beaker, and the residual solvent is

evaporated. The residue is dried for 30 min at 100°C. The amount of caffeine is determined by weighing or by nitrogen determination using the Kjeldahl method.

The Levine method is used in preparing samples for the spectrophotometric determination of residual caffeine in decaffeinated coffees. An acidic Celite column is prepared by adding 2 ml of sulfuric acid ( $4 \text{ mol l}^{-1}$ ) to 2.0 g of Celite 545. The mixture is transferred into a 25 mm ID  $\times$  250 mm glass column plugged with fine glass wool at both ends. A basic column is prepared by mixing 3 g of Celite 545 with 2 ml of sodium hydroxide ( $2 \text{ mol l}^{-1}$ ); this is then transferred into a 25 mm ID  $\times$  250 mm glass column with a fine glass wool plug at the bottom. Coffee sample (1.0 g decaffeinated coffee or 0.5 g decaffeinated soluble coffee) is treated with 5 ml of ammonia solution and heated over a steam bath for 2 min. Six grams of Celite 545 is added to adsorb the alkaline mixture and the alkali–coffee–Celite mixture is applied directly onto the basic Celite column. The basic column is mounted on top of the acidic column. Water-saturated ether (150 ml) is passed through both basic and acidic columns. The acidic column is washed with an additional 50 ml of ether. The ether portions are discarded. Caffeine is eluted from the acidic column with 50 ml of water-saturated chloroform solution.

*Theobromine in cocoa* The Wadsworth method is used for the extraction of theobromine from cocoa powder or defatted cocoa products. Ten grams of sample is put in a porcelain dish and mixed with 2–3 g of fresh calcined MgO. Water (9–20 ml) is added, a few milliliters at a time, and mixed thoroughly to ensure uniform consistency and wetting of all particles. The mixture is heated on a steam bath for 30 min, with mixing at regular intervals to maintain uniform consistency and to prevent drying. After heating, the mixture is transferred into a 250 ml flask and refluxed with 150 ml of tetrachloroethane for 30 min. The hot extract is filtered into a 200 ml flask. The residue is refluxed with three additional portions of tetrachloroethane (120 ml) for up to 30 min. Solvent in the 200 ml flask is removed by distillation after each reflux and filtration step, until the volume is reduced to between 3 ml and 5 ml. The residue is cooled and treated with 65 ml of ether, mixed by swirling the flask. The ether mixture is stoppered and left standing until the supernatant is clear (up to an hour or more). The ether mixture is filtered with preweighed filtered paper and dried at 100°C. The weight of precipitated theobromine collected after filtration and removal of ether is determined by weighing. A correction of 0.004 g is added to account for the amount of theobromine dissolved in the ether.

An aqueous extraction method is used to extract both the theobromine and caffeine from defatted cocoa products for analysis by liquid chromatography (LC). In this method, 0.6 g of cocoa is placed in an extraction tube with a polytetrafluoroethylene-lined screw cap. The sample is extracted twice with 30 ml portions of petroleum ether, centrifuged, and the ether phase, which contains fat, is discarded. The residue, after removing all residual solvent, is transferred into an Erlenmeyer flask with boiling chips and added with 95 ml of water. The mixture is boiled for 25 min. After cooling, several portions of the mixture are transferred into screw-capped centrifuge tubes and centrifuged at 2000 g for 5 min. The supernatant is filtered through a 0.45  $\mu\text{m}$  membrane filter, and the filtrate is analyzed by LC.

### Organic Acids, polyphenols, and lipids

**Chlorogenic acids in coffee** One gram of roasted ground coffee is transferred into a 750 ml Erlenmeyer flask. Boiling water (400 ml) is added, and the mixture is boiled gently for 15 min, then cooled rapidly under cold tap water. The mixture is transferred into a 500 ml volumetric flask, diluted to volume, and filtered. The first 25–50 ml of the filtrate is discarded. Chlorogenic acid in the filtrate is determined by a spectrophotometric or chromatographic method. For soluble coffee solids, 0.35 g of sample is transferred into a 500 ml flask and diluted to volume. For green coffee, 0.7 g of ground sample is extracted with petroleum ether (25 ml) in a 50 ml centrifuge tube. After mixing and centrifugation, petroleum ether is removed by decanting. The residue is washed with two additional portions of petroleum ether. Residual solvent is removed by drying under a stream of dry air. The residue is transferred with a few milliliters of water into the 750 ml Erlenmeyer flask. Boiling water is added and the sample is extracted following the same procedure as in roasted coffee. Alternative extraction procedures using aqueous alcohols have also been employed.

**Cocoa fat and lipids** The lipid components in cocoa are extracted into petroleum ether by either the Knorr Tube method or by Soxhlet extraction. Both are adopted by AOAC, and the latter method by both AOAC and the Office International du Cacao et du Chocolat. In the Knorr Tube method, 2–3 g of cocoa powder or grated chocolate product is transferred into a Knorr Tube fitted with 6 mm of tightly packed mat of washed asbestos filter. The extraction tube is connected to suction by a two-way stopcock, and the stem of the extraction tube is connected to a preweighed Erlenmeyer flask. The extraction tube is filled up to two-thirds capacity by petroleum ether.

After thorough mixing, the ether phase is separated by standing, and drained into the Erlenmeyer flask by suction. The extraction process is repeated up to 10 times for complete extraction of fat. The solvent is evaporated and the sample is dried at 100°C. The amount of fat in the sample is determined by weighing.

In the Soxhlet method, 4–5 g of cocoa powder is placed in a 500 ml beaker and treated with 45 ml of boiling water with stirring. The mixture is acidified with hydrochloric acid (8 mol l<sup>-1</sup>, 55 ml). Antibumping beads are added and mixture is boiled for 15 min. The acid digest is filtered after boiling and cooling. The beaker is rinsed several times with water until the filtrate is free of chloride, as tested by adding 0.1 mol l<sup>-1</sup> silver nitrate. The filter paper with the collected residue is put in an extraction thimble and dried in a small beaker at 100°C for 6–18 h. The dried extraction thimble is placed in a Soxhlet extractor. The digestion beaker and drying beaker are washed with 50 ml portions of petroleum ether into the extraction thimble. The sample is refluxed for 4 h with gentle heat. The extraction solvent is siphoned into a preweighed Erlenmeyer flask. The solvent is subsequently removed by distillation on a steam bath, and the flask is dried at 100°C for up to 2 h. The amount of fat is determined by weighing.

**Tannins and pigments in cocoa** Tannins and coloring matters in defatted cocoa powder and related products can be extracted by shaking consecutively with 150 ml and 100 ml portions of acidified 82% ethanol (10 ml HCl and 432 ml ethanol, diluted to 500 ml with water), at 55°C. The solvent is separated by centrifugation. Ethanolic extracts are pooled and evaporated. Alternatively, tannins and catechins in acetone extract can be precipitated with cinchonine sulfate and measured gravimetrically. In this extraction method, 25 g of sample is extracted overnight with 40% acetone (200 ml, cold). The acetone extract is filtered through a Whatman No. 41 paper. The residue is washed with 20 ml of 40% acetone. Water is added to make up to 250 ml. Saturated cinchonine sulfate (150 ml) is added to 25 ml of tannin-containing filtrate. The precipitate formed is filtered off and dried. The dried weight is multiplied by 0.534 to obtain the tannin content.

**Catechins, polyphenols, and tannins in tea** Catechins and related flavanols are water soluble, and can be extracted by boiling with water, or by shaking with aqueous acetone.

**Volatile and aromatic components** Volatile and aromatic components in coffee are concentrated by

passing purified helium gas directly over the sample (50 g of ground coffee) or the beverage (made from 2 g of coffee). The gas is aspirated through an adsorption tube (60 mm  $\times$  4 mm ID) containing 90 mg of a porous polymer (Tenax, 60/80 mesh, preconditioned for 24 h at 300°C in helium). Aromatic components are desorbed by heating and swept into the injection port of a gas chromatograph for the analysis of individual components.

Volatile and aromatic components of tea and tea infusion are also concentrated by aqueous distillation and the cold-trapping method. In this method, the sample is suspended in water in a 2 l round-bottomed flask connected to a rotary evaporator. The condenser is connected to cold traps containing freezing mixture (–15°C to –18°C) or dry ice–acetone mixture (–78°C). The aqueous mixture is distilled twice at 70°C, 25–30 mmHg. The distillate is saturated with sodium chloride and extracted with ether. The ether extract is dried over anhydrous sodium sulfate and concentrated by distillation of the solvent at 40°C. Components in the ether extract are analyzed by gas chromatography.

## Analytical Procedures

### Coffee

**Caffeine** The analyses of methylxanthines in coffee and tea are conducted: (1) by measuring the total nitrogen in extracts, either derived from the Bailey–Andrew extraction in the case of caffeine or by the Wadsworth method in the case of theobromine; (2) by spectrophotometric methods; and (3) by chromatographic methods, including thin-layer chromatography (TLC), LC, and gas chromatography (GC). The major advantage of chromatographic methods over spectrophotometric methods is the ability of the former to separate and quantify several methylxanthines (caffeine, theophylline, and theobromine) simultaneously.

*Spectrophotometric methods for the analysis of caffeine* Caffeine is quantified spectrophotometrically by measuring the ultraviolet (UV) absorbance at wavelengths between 270 and 280 nm. The major drawback of such methods is the presence of interfering substances. Such interferences can be reduced, but not eliminated, by using derivative techniques. Sample cleanup by various types of columns and background correction procedures is used to purify caffeine before spectrophotometric measurement. For example, in the Levine method, sample cleanup is achieved by a series of acidic and basic Celite columns. This method is adopted by AOAC for the analysis of

caffeine in decaffeinated coffees. Other methods using alumina columns (Kum–Tatt method), alkaline extraction, and combinations of various types of columns have also been used in sample cleanup.

*Thin-layer chromatography* Methylxanthines analysis by TLC has the advantages of high sample throughput and low cost. The major disadvantage of TLC methodology is its nonquantitative nature. Separation is achieved by chromatography on silica gel plates, using a variety of organic solvent mixtures as eluting solvents. Some typical solvent mixtures are: chloroform–methanol (9:1; v/v); benzene–acetone (3:7; v/v); chloroform–carbon tetrachloride–methanol (8:5:1; v/v/v); chloroform–ethanol–formic acid (88:10:2; v/v/v). Separation of methylxanthines has also been achieved using paper chromatography or with cellulose plate using a butanol–hydrochloric acid–water (100:11:28; v/v/v) mixture.

*Liquid chromatography* Analysis of methylxanthines by LC is carried out with C<sub>18</sub> reversed-phase columns, with acidic buffer mobile phases, and monitoring by UV absorption at ~270–280 nm, or at 254 nm. The LC procedure adopted by the AOAC for the analysis of caffeine utilizes a  $\mu$ Bondapak (Waters) C<sub>18</sub> column, with a mobile phase of water–methanol–acetic acid (74:25:1; v/v/v) and detection at 280 nm. Other solvent systems, such as water–acetonitrile–acetic acid (81:18:1; v/v/v) and phosphoric acid (7 mmol l<sup>–1</sup>)–acetonitrile–methanol (92:4:4; v/v/v), have also been used successfully in separating methylxanthines in foods and beverages. LC methods using normal-phase columns, such as Lichrosorb Si-60, with mobile phase composition of chloroform–2-propanol–acetic acid (96:2:2 or 92:7:1; v/v/v) and detection at 275–280 nm have also been applied to the analysis of methylxanthines, but are less robust. Quantification of methylxanthines is achieved by using either external standards or by using xanthine derivatives as internal standards; examples are 8-chlorotheophylline and 8-hydroxy-ethyltheophylline.

*Gas chromatography* The AOAC method for the analysis of caffeine by GC uses a packed glass column, 6 ft (~180 cm) in length by 4 mm ID, packed with 10% DC-200 oil on 80–100 mesh Gas Chrom Q, using nitrogen carrier gas and a thermionic potassium chloride detector. The injector temperature is 220°C, the column temperature is 190°C, and the detector temperature is 220°C. A wide variety of column-packing materials and detection modes can be used. For example, separation of caffeine, theophylline, and theobromine can be achieved with

3% OV-17 on Gas Chrom Q (100–120 mesh) by isothermal or temperature programming, with electron-capture detector, flame ionization detector (FID), or nitrogen–phosphorus detector (NPD).

### Chlorogenic acids

**Spectrophotometric analysis** Spectrophotometric determination of total chlorogenic acid content in green coffee extract is conducted by measuring the absorbance at 324 nm, as in the AOAC standard procedures. Modification of this method by purification and extraction of the sample has been applied to eliminate interferences in roasted coffee. The formation of colored complexes with borates, molybdates, and periodates enables more accurate determination of specific classes of chlorogenic acids.

**Gas chromatography** The complete separation and analysis of chlorogenic acids by capillary GC requires derivatization of the phenolic or carboxylic acid functions by silylating agents, such as hexamethyldisilazane or N,O-bis(trimethylsilyl)acetamide, or a mixture of both.

**Liquid chromatography** Analyses of chlorogenic acids are carried out with reversed-phase LC systems, both in gradient and isocratic modes. The typical analytical system employs C<sub>18</sub> columns of 5 µm packing, with a mobile-phase gradient of 25–47.5% methanol in pH 2.5 citrate buffer (0.025 mol l<sup>-1</sup>), or isocratic elution with 30% methanol in pH 2.5 citrate buffer (0.025 mol l<sup>-1</sup>), with UV detection at 310–330 nm.

**Volatile and aromatic components** Separation of volatile components is achieved on either fused silica capillary columns or packed columns. Individual volatile components are detected with a FID and identified by the use of reference standards. Methods using specific detectors, such as the NPD, sulfur-specific flame photometric detector, and mass-selective detector (MSD) have also been used. The MSD has the additional advantage of providing structural identification of the individual components.

### Cocoa

**Theobromine and caffeine** Separation and quantitative analyses of theobromine and caffeine are carried out using C<sub>18</sub> reversed-phase columns, with monitoring by UV absorption at 280 nm. In the AOAC method, a Waters LC system is used, with a µBondapak C<sub>18</sub> column, 30 cm length × 4 mm ID and 10 µm packing. The mobile phase is methanol–acetic acid–water (20:1:79; v/v/v) at 1 ml min<sup>-1</sup> with

a nominal back-pressure of 2000 psi (~14 000 kPa). Concentrations of theobromine and caffeine in cocoa extracts are determined from a calibration graph, using the external standard method.

**Cocoa fat and lipids** In AOAC methodologies, the composition of fat and fatty acids in cocoa fat extracts are analyzed and characterized by physicochemical methods, including refractive index, melting point, saponification value and unsaponifiable material, iodine number, Reichert–Meissl and Polenske values.

**Volatile and aromatic components** Cocoa volatile and aromatic components are analyzed by capillary GC, with samples derived from headspace enrichment or cold-trapping techniques. Analysis is similar to that of coffee volatiles; FIDs are used and identification is by the use of reference compounds.

### Tea

**Methylxanthines: caffeine and theophylline** The amount of caffeine in tea is determined by spectrophotometric and chromatographic methods, as described above for coffee. Separation of caffeine from theophylline is achieved by chromatographic methods.

**Polyphenols: catechins and flavanols** Flavanols and tea polyphenols are commonly analyzed using paper chromatography, TLC, and LC. GC has also been used, but derivatization of the hydroxyl groups with silylation is required to increase the volatility of these analytes.

**Paper chromatography and thin-layer chromatography** Tea flavanols can be separated by two-dimensional paper chromatography, using water as the first dimension solvent, and a mixture of butanol–acetic acid–water (4:1:5; v/v/v) as the second dimension. A similar procedure can be carried out using TLC with cellulose plates. Different flavanol components are visualized by fluorescence under UV radiation, either before or after exposure to fuming ammonia. Other visualizing agents are bis-diazotized benzidine and vanillin.

**Liquid chromatography** Separation and quantitative analysis of flavanols and polyphenols may be conducted by C<sub>18</sub> reversed-phase LC methods, using either isocratic or gradient modes. In one example of the isocratic separation method, the solvent system used consists of acetic acid–methanol–dimethylformamide–water (1:2:40:157; v/v/v/v). Eluting peaks are monitored by UV absorption at 254 nm.

*Gas chromatography* The utility of GC for the analysis of catechins and polyphenols is quite limited, given the polar and nonvolatile nature of these compounds. Derivatization of a polyphenol extract with silylating agent and subsequent separation of the trimethylsilyl derivatives of flavanols can be achieved by chromatographing on a glass column 5 ft (~150 cm) in length  $\times$  4 mm ID packed with 3% OV-1 on diatomite.

**Tannins, theaflavins, and thearubigens** Tannins and theaflavins are pigmented products in black tea formed after oxidation and condensation of green tea flavanols during the fermentation process. These compounds are analyzed by spectrophotometric, colorimetric, and chromatographic methods, using LC and GC.

*Spectrophotometric and colorimetric methods* Spectrophotometric analysis of theaflavins is carried out at 380 and 460 nm on isobutyl methyl ketone or ethyl acetate extracts of black tea infusions. Theaflavins are also determined by using Flavognost reagent (diphenyl boric acid ethanolaamine), which forms a green chromophore by reacting with the benzotropolone nucleus of theaflavins. The color developed is measured at 600 nm.

*Liquid chromatographic methods* Separation and quantitative analysis of theaflavins and thearubigens has also been achieved by gel permeation chromatography on Sephadex LH-20, monitoring the eluting peaks at 380 nm. Reversed-phase LC separation has also been conducted using a C<sub>18</sub> column, with a mobile phase consisting of 29% aqueous acetone and 1% acetic acid.

## **Analysis of Coffee, Cocoa, and Tea for Quality Assurance Purposes**

### **Coffee**

The flavor and aroma qualities of the common coffee beverages are dependent on the source of the coffee bean used, soil and climatic conditions, as well as the duration and temperature of roasting. The determination of the quality of roasted coffee is mainly by tasting of the brew by professional tasters. Such processes are qualitative only. Chemical analysis of coffee quality is based on headspace analysis of the aroma components of roasted or brewed coffee. For instance, drastic decreases in methylfuran and methylethylketone in coffee aroma have been observed in roasted and ground coffee within a few days, which may be correlated to coffee staleness. A

decrease in the ratio of 2-methylfuran to 2-butanone in coffee aroma with time has also been observed. However, the use of such ratios of individual aroma components as measures of coffee quality has not been officially established.

### **Cocoa**

Quality evaluation of cocoa bean and cocoa powder is by visual inspection for contamination, moldiness, and by aroma/flavor and tasting. Physical analysis of cocoa bean and cocoa powder includes analysis for total moisture (<8%) and fat (<55%). Additionally, the quality of cocoa is characterized by the iodine number (degree of unsaturation of the fatty acid components), unsaponifiable matter, and GC analysis (for volatile and aroma components).

### **Tea**

Quality assessment of tea is conducted by evaluation of the color and appearance of the tea leaves and the tea infusion formed, as well as by GC analysis of the aroma of both the tea leaves and the infusion. For example, (Z)-3-hexenyl hexanoate is a major contributor to the aroma of fresh green tea. This component is found to decrease with storage. The astringent taste of tea is mainly due to the presence of unoxidized flavanols and polyphenolics (e.g., catechins). Gradual and continued oxidation of these components with storage time would result in changes in both color and taste of the product. The brothy taste of green tea is due to the presence of amino acids, notably L-threonine. A decrease in the amino acid contents during storage would also result in deterioration of quality.

## **Limitations of Current Technology**

Despite the fact that major components in coffee, cocoa, and tea can be analyzed and measured by the methodologies outlined above, there are many minor components in these beverages that have not been extensively studied. For example, roasting of coffee induces caramelization, condensation, pyrolysis, and Maillard reactions; the nature and composition of these reaction products (collectively termed melanoidins) are dependent on the temperature and duration of roasting. Although these reaction products in roasted coffee constitute as much as 30% of dry weight, their chemical identities are largely unknown. The relationship of melanoidin content to quality, taste, and flavor of the product is not well understood and analytical procedures for determining these components are lacking. The manufacturing processes of black tea involve extensive oxidation and polymerization of

polyphenols and results in the formation of the aflavins and thearubigens. The formation of these condensation products is dependent on the duration of oxidation during fermentation. Analytical methods for the characterization of aroma components remain to be established and the relationship between individual components and product quality has yet to be elucidated.

This article is a revision of the previous-edition article by Xuejun Zhang, pp. 1504–1512, © 1995, Elsevier Ltd.

## Introduction

Alcoholic beverages comprise a large group of beverages that contain varying amounts of alcohol (ethanol). Alcoholic beverages produced on an industrial scale include beer, wine, and China rice wine, and distilled spirits such as brandy, whisky, rum, gin, cognac, vodka, tequila, pisco, and China distilled spirit. The components of alcoholic beverages are highly complex and over 1300 compounds have been identified in various beverages.

The constituents of each alcoholic beverage can be divided into major, minor, or trace components. The major constituents usually consist of ethanol and water. The minor or trace constituents are fusel alcohols, organic acids, carbonyl compounds, esters, aldehydes, lactones, sulfur compounds, sugars, preservatives, and colorants. There are two general approaches to analyzing the components of alcoholic beverages. The first, and most usual, is by using

chemical and physiochemical analysis. The other is to use sensory evaluation. In recent years, instrumental analytical methods have become an important tool for analyzing minor and trace constituents of alcoholic beverages. The most widely used methods are ultraviolet (UV)–visible spectrophotometry, gas chromatography (GC), liquid chromatography (LC), mass spectrometry (MS), and paper chromatography, and thin-layer chromatography.

This article will review the methods applied for the determination of major and minor components in alcoholic beverages.

## Sensory Assessment

Sensory assessment is a scientific discipline used to evoke, measure, analyze, and interpret responses to those properties of a substance (food or beverage) that are perceived by the five human senses: sight, smell, taste, touch, and hearing. Even though individual judgments are subjective, the techniques of sensory evaluation use objective scientific testing methods principally based on working with a panel of assessors. Two types of analytical objective tests can be observed: (1) The discriminative tests: is there a difference between several products? (2) The

polyphenols and results in the formation of the aflavins and thearubigens. The formation of these condensation products is dependent on the duration of oxidation during fermentation. Analytical methods for the characterization of aroma components remain to be established and the relationship between individual components and product quality has yet to be elucidated.

## Introduction

Alcoholic beverages comprise a large group of beverages that contain varying amounts of alcohol (ethanol). Alcoholic beverages produced on an industrial scale include beer, wine, and China rice wine, and distilled spirits such as brandy, whisky, rum, gin, cognac, vodka, tequila, pisco, and China distilled spirit. The components of alcoholic beverages are highly complex and over 1300 compounds have been identified in various beverages.

The constituents of each alcoholic beverage can be divided into major, minor, or trace components. The major constituents usually consist of ethanol and water. The minor or trace constituents are fusel alcohols, organic acids, carbonyl compounds, esters, aldehydes, lactones, sulfur compounds, sugars, preservatives, and colorants. There are two general approaches to analyzing the components of alcoholic beverages. The first, and most usual, is by using

chemical and physiochemical analysis. The other is to use sensory evaluation. In recent years, instrumental analytical methods have become an important tool for analyzing minor and trace constituents of alcoholic beverages. The most widely used methods are ultraviolet (UV)–visible spectrophotometry, gas chromatography (GC), liquid chromatography (LC), mass spectrometry (MS), and paper chromatography, and thin-layer chromatography.

This article will review the methods applied for the determination of major and minor components in alcoholic beverages.

## Sensory Assessment

Sensory assessment is a scientific discipline used to evoke, measure, analyze, and interpret responses to those properties of a substance (food or beverage) that are perceived by the five human senses: sight, smell, taste, touch, and hearing. Even though individual judgments are subjective, the techniques of sensory evaluation use objective scientific testing methods principally based on working with a panel of assessors. Two types of analytical objective tests can be observed: (1) The discriminative tests: is there a difference between several products? (2) The

descriptive tests: what is the difference and how big is it?

The sensory assessment of alcoholic beverage, such as wine or beer, has, in general, three basic steps (except the decision on rating method):

1. Visual inspection: Checking if the container is bottle full and examination for transparency or sediment. After pouring the liquid into the glass (for wine there exist ISO standardized glasses), an additional appearance inspection follows. The sample is oriented against a bright background. In the case of wine, the sample is viewed at an angle of 30–45°; in the case of beer it is agitated to get a generous head. The appearance is scored later. One examines absence of haze, color shade and depth, viscosity, effervescence, or head retention. Visual inspection may seriously affect the subsequent evaluation steps, so one needs to be careful not to prejudge the beverage based on a visual inspection of the bottle.

2. Smell: There are various modes of odor evaluation. In the case of wine, it is recommended not to swirl first, as the most volatile compounds are perceived in this way. The nature and intensity of odors is recorded according to the rating system. Successive swirling should promote release of the heavier polar compounds that are retained in the hydroalcoholic solution more than in the apolar ones. Some tasters hold the glass between the hands when the beverage is too cold. The impressions are recorded yet again.

3. In-mouth sensations: The most complex task is the evaluation of simultaneously appearing sensations while tasting the beverage in the mouth. After coating the inside of the mouth with the liquid, one should score: (1) Taste and mouth-feel (body) – presence of taste sensations (sweet, acid, and bitter taste: their duration and changes in quality and intensity) and tactile sensations (astringency, prickling, body, temperature, and heat). (2) Odor – rating of beverage odors at the warmer temperatures of mouth, which increases volatility of odorants, before swallowing. Mainly the differences between the in-mouth and in-glass odor features are observed. (3) Aftersmell – rating of odor sensations after swallowing the liquid and expiring through the nose. The final stage of wine tasting is termed finish. It is the final impression from the wine (good or bad), may include odor-related, hedonic (e.g., flourish), or time-related terms (e.g., short finish). Typically, the longer the finish the more highly rated the wine.

Sensory richness of alcoholic beverages, especially of wine, promoted an intense effort to unveil the

chemical background behind these percepts. As the impression derived from sensory evaluation is mainly governed by olfaction, the area of volatile compounds was the most investigated. Especially the performance and wide accessibility of GC and MS allowed identifying many volatiles, which could potentially contribute to the sensations experienced during wine or beer tasting. However, it was the introduction of GC–olfactometry in the 1970s that radically advanced the discovery of the real key compounds.

The establishment of odor units (a ratio of actual concentration of odorant to its threshold concentration) was also beneficial, even if in reality more emphasis is given to intensity ratings.

The most useful flavor descriptive procedure has so far turned out to be the development of flavor vocabulary precisely defined for each product. It is important to find sufficiently refined terms for the characteristic sensory properties of the specific alcoholic beverage. There are various intensity rating strategies in the sensory assessment practice. Perhaps the most widely used are the aroma wheels. The first was M.C. Mailgaard's 'Beer Flavor Wheel', jointly adopted in the 1970s by the European Brewery Convention, the American Society of Brewing Chemists, and the Master Brewers Association of America. A similar attempt was made in the 1980s by A. Nobel's 'Wine Aroma Wheel'. These systems provide standardized flavor descriptors and recipes for their reconstruction. Various methods were proposed for flavor profiling, among which the Quantitative Descriptive Analysis (QDA<sup>TM</sup>) and Free Choice Profiling are prominent. The reliability of the results must be tested statistically even when using threshold values or relative values like odor unit values. Statistics are also needed in the different profile techniques, both to examine how judges employ the methods and to develop the terminology.

Endeavors have been made to find a link between two data sets (sensory versus instrumental data). The common goal of these tools is to discover the components or parameters whose variation explains the variation of sensory characteristics. The most useful statistical methods used for such purpose are partial least squares regression and generalized procrustes analysis. From a practical point of view, the models can be used to complement sensory assessment in routine quality control or in product and process development work. Regression-based statistical techniques are often used in conjunction with GC to distinguish well-known brands of alcoholic beverages from less expensive ones to detect counterfeit products.

## Proof and Extract

The proof of an alcoholic beverage is a measurement of its ethanol content. The proof of spirit and wine is defined as the percentage by volume of ethanol. The traditional method for determination of proof uses a pycnometer or a small, accurately graduated hydrometer. Recently, the European Community has adopted a reference method for ethanol determination in spirits, based on two steps. The first step is a prescribed distillation stage and the second step allows a choice from three different methods of measuring the density of the distillate: (1) pycnometry: time consuming and susceptible to error; (2) electronic densimetry: measurement of the oscillations of a vibrating U-tube, this method is simple and fast; (3) densimetry using hydrostatic balance: this method is also fast with the new generation of instrumentation.

The extract of an alcoholic beverage is a measurement of its nonvolatile compounds. The extract of a wine is the most important among the alcoholic beverages. Wine extract is composed of sugars, fixed acids, organic salts, and other substances. Its value is a measure of wine quality. The traditional method of determining wine extract is drying at 100°C. The method has the disadvantages of being time consuming and limited to wines having an extract not greater than 6 g per 100 ml. It is being used less frequently today.

Of the two AOAC methods (Official Methods of Analysis of the Association of Official Analytical Chemists) to determine wine extract, the more convenient one relates the extract of wine to the specific gravity (relative density) of the dealcoholized wine. In spirits, the reference method adopted by EU legislation is gravimetry, involving weighing the residue left by evaporation of the spirit on a boiling water bath and drying in a drying oven. The method is not suitable for liqueurs because of their high sugar content.

Some recent and convenient procedures have been used to determine both ethanol content and extract. Regarding ethanol, an AOAC-approved method exists for the determination of ethanol in wine based on GC and the technique is very precise and accurate. An increasingly popular technique is the use of near-infrared spectroscopy. Instruments are commercially available allowing the determination of ethanol and other common parameters in wine.

## Determination of Alcohols

Alcohols in alcoholic beverages mainly consist of aliphatic monohydric alcohols and di- and trihydric alcohols. Methanol and fusel oil in alcohols are

determined but ethanol is determined as a proof in a routine analysis of alcoholic beverages.

Methanol is ubiquitous and is usually a minor component in alcoholic beverages, but some distilled alcoholic beverages produced from potato and stone fruits, such as cherries and plums, are exceptions and may contain rather large amounts. Large amounts of methanol have also been determined in some fortified wine, China distilled spirit, distilled wine, and brandy.

Higher alcohols from propanol up to 3-methyl-1-butanol (isoamyl alcohol), frequently encountered in so-called fusel oil fractions, are considered to be an important aroma factor, and for this reason they have been determined in a large number of beers, wines, and distilled alcoholic beverages. Because higher alcohols are believed to have a marked effect on the volatile flavor of distilled beverages, numerous papers have been published describing both the relative and absolute compositions of fusel oil fractions.

Generally, colorimetric methods and GC are used for the determination of methanol and fusel oil in distilled alcoholic beverages and spirits.

According to the procedure presented in the AOAC method, methanol is oxidized to formaldehyde by a potassium permanganate solution. The aldehyde formed is allowed to react with chromotropic acid in strongly acidic solution to form a colored product. Its absorbance is measured spectrophotometrically at 575 nm.

The colorimetric methods recommended for the determination of total fusel oil contents in beverages are based on a color reaction. In this reaction, 2-methyl-1-propanol, 2-methyl-1-butanol, and 3-methyl-1-butanol lose water during heating in a strongly acidic solution and the unsaturated hydrocarbons formed yield colored complexes with vanillin, salicylaldehyde, and 4-dimethyl-aminobenzaldehyde. The absorbance is measured spectrophotometrically at 445 and 560 nm.

GC provides a means of evaluating small amounts of methanol in beer, wine, and distilled alcoholic beverages. It is the most convenient method to determine single fusel oil and methanol in beverages simultaneously.

Although, direct injection with GC-flame ionization detection (FID) is sensitive enough to quantify methanol and fusel oils, it is advisable only for spirits because of the dirt accumulated in the injection port when beer, wine, or liqueurs are analyzed. Thus, liquid-liquid extraction has been widely applied to separate and concentrate fusel oil from beer, wine, and distilled alcoholic beverages, followed by GC determination of the compounds. Nowadays, many simpler and online extraction techniques are applied

**Figure 1** Chromatogram showing baseline resolution of the 13 alcohols in the order listed in **Table 1**. Chromatographic conditions: 6 ft ( $\sim 180$  cm)  $\times$  2 mm ID glass column packed with 0.2% Carbowax 1500 on Carbowax C (80–100 mesh); column temperature held at 55°C for 4 min, then programmed to 95°C at 2°C min<sup>-1</sup>.

in alcohol determination such as liquid microextraction, solid-phase extraction (SPE), and solid-phase microextraction (SPME).

The direct GC method is the simplest and fastest for simultaneous determination of methanol, acetaldehyde, and fusel oil. The efficiency and resolution of GC has improved with the development of more efficient supports and liquid phases. Liquid phases, such as Carbowax and combinations of two liquid phases, have been most useful for determining fusel oil. **Figure 1** shows the results obtained by using a single direct injection procedure for separating and quantifying methanol and fusel oil whisky. Baseline resolution was obtained for each of the 13 alcohols (**Table 1**) in 25 min. 1-Butanol was chosen as the internal standard with a relative retention time of 1.0.

Alcohols are also analyzed by LC; in most cases the choice of the column falls on an ionic-exchange resin of the styrene-divinyl benzene polymer type, to which has been linked a functional group of the sulfonic type in the form H<sup>+</sup> or with another suitable cation. Since the separation of alcohols is performed very often together with other analytes, such as organic acids and sugars, the choice of the type of detector also takes into account their chemical-physical properties. Usually, the choice is the UV detector, the refractive index detector, or the electrochemical detector (EC). The use of LC allows the determination of less volatile alcohols such as glycerol in wine and beer, which could be difficult to analyze by GC.

**Table 1** Gas chromatographic retention times (RRTs) of alcohols (relative to 1-butanol)

IUPAC name	Common name	RRT
Methanol	Methyl alcohol	0.03
Ethanol	Ethyl alcohol	0.08
2-Propanol	Isopropyl alcohol	0.18
1-Propanol	<i>n</i> -Propyl alcohol	0.26
2-Methyl-2-propanol	<i>t</i> -Butyl alcohol	0.34
2-Butanol	<i>s</i> -Butyl alcohol	0.60
2-Methyl-1-propanol	Isobutyl alcohol	0.72
1-Butanol	<i>n</i> -Butyl alcohol	1.00
3-Pentanol		1.43
2-Pentanol	<i>s</i> -Amyl alcohol	1.58
2-Methyl-1-butanol	Active amyl alcohol	1.69
3-Methyl-1-butanol	Isoamyl alcohol	1.81
1-Pentanol	<i>n</i> -Amyl alcohol	2.08

## Aliphatic Carbonyl Compounds

Aliphatic carbonyl compounds consist mainly of aldehydes and ketones. A large number of aliphatic aldehydes have been shown to be present in alcoholic beverages. Among the aldehydes determined quantitatively acetaldehyde is the major component, and generally constitutes more than 90% of the total aldehyde content of the beverage. For this reason it could be expected that acetaldehyde is of importance

to the aroma and is often associated with improved quality.

Ketones form a minor fraction in alcoholic beverages. Ketones can be said to be potential aroma compounds. In particular, diketones such as 2,3-butanodione and 2,3-pentanodione are of great importance to the aroma of alcoholic beverages because of their low sensory threshold values. Those aldehydes with 8–10 carbon atoms, such as (*E*)-2-nonenal, octanal, nonanal, decanal, or (*E,Z*)-nonadienal, are also strong odorants, related with important off-flavors.

Titrimetric and colorimetric methods are available for the determination of aldehyde contents in alcoholic beverages. An iodimetric method has been used for the determination of the total aldehyde content of wines. A modified iodimetric titration method is included in the methods of AOAC. In order to avoid the reactions of interfering substances, aldehydes are separated by distilling an aliquot of wine into a neutral hydrogensulfite solution. After the excess of hydrogensulfite has been titrated with an iodine solution at pH 2, hydrogensulfite is released from its aldehyde addition compound at pH 9 and titrated with iodine solution.

Different colorimetric methods have been developed for the determination of aldehyde and diketone contents in alcoholic beverages. Fuchsin, piperidine, 3-methylbenzothiazole-2-one hydrazone, 2-naphthol, and creatine have generally been used as reagents to produce colored compounds, the absorbances of which are measured at a wavelength between 630 and 660 nm or 500 and 550 nm.

As has been previously said, 2,3-butanodione (diacetyl) is an important aroma of alcoholic beverages, it has not been studied and measured extensively in the past because of analytical difficulties in the quantitation caused by its highly volatile nature, chemical instability, and interference of other compounds. Colorimetric methods to measure diacetyl have been widely used in the past. These methods involve steam distillation to isolate diacetyl from the matrix. However, distillation has the disadvantage of incomplete isolation of diacetyl from other closely related compounds that will result in an overestimation of its concentration. A fluorometric method was developed to improve upon the lengthy distillation methods that involve derivatization. Although acetaldehyde and its acetal can be determined by direct injection GC-FID in spirit drinks (EU reference method for spirits), most chromatographic methods for minor aldehydes implicate also derivatization. While a very sensitive and accurate method based on SMPE without derivatization and MS detection has been developed, it requires the use of

deuterated diacetyl- $d_6$  as an internal standard, not easily available.

Due to the poor chromatographic and MS properties of higher aldehydes and ketones, most analytical methods are based on GC-MS or GC-ECD analysis of chemical derivatives. An added analytical problem is the high content of major carbonyl compounds, such as acetaldehyde, pyruvic acid, acetone, or diacetyl compared with C8-C10 aldehydes. Most of the methods previously developed for the analysis of carbonyl components in wine are based on the GC-MS or GC-ECD analysis of oximes formed by reaction with *O*-(2,3,4,5,6-pentafluorobenzyl)hydroxylamine hydrochloride, although other derivatization reagents have been explored such as 2,4-dinitrophenyl-hydrazine or cysteamine. On the other hand, the analysis of (*E*)-2-nonenal in wine, or of some higher methyl ketones in cognac, has been carried out by performing the chemical reaction over an organic extract obtained from the wine or cognac. All these methods use tedious liquid-liquid extractions. Nevertheless, several authors have shown the potential of direct derivatization of carbonyls on a solid phase, particularly in SPME- and SPE-based strategies.

## Organic Acids

Organic acids in alcoholic beverages can be classified into volatile and fixed acids and may be of great importance. It has been found that some organic acids significantly influence the odor and taste of alcoholic beverages. Any substantial increase in the volatile acidity in wines seems to be a consequence of the activity of spoilage microorganisms. For this reason statutory restrictions exist in many countries for the maximum amounts of the volatile acids in wine.

Organic acids consist of aliphatic monobasic carboxylic acids from formic acid up to the  $C_{18}$  acids; aliphatic monobasic hydroxyl acids such as lactic acid; aldonic and uronic acids such as gluconic, glucuronic, and galacturonic acids; aliphatic monobasic oxo acids, mainly including succinic, malic, citric, and tartaric acids.

Distilled and undistilled beverages contain acetic acid in abundance. Frequently it amounts to 40–95% of the total volatile acids. Although the greatest part of the volatile acidity in wine consists of acetic acid, the remaining acids are nonetheless important aroma compounds. Many short-chain and long-chain acids, and in particular the branched-chain acids, have an appreciably strong odor.

Methods employed for the determination of organic acids in alcoholic beverages include

titrimetric, colorimetric, enzymatic, paper chromatographic, thin-layer chromatographic, gas chromatographic, and liquid chromatographic procedures, as well as GC combined with MS. Titrimetric methods are mainly employed to determine the total volatile acids from formic acid up to C<sub>18</sub> acids. In the procedure, the volatile acids are isolated from alcoholic beverages by steam distillation followed by titration with a strong base. In order to concentrate the volatile acids methods such as microdiffusion, reduced pressure, or vacuum steam distillation can be used.

Titrimetric methods have also commonly been proposed for the determination of fixed and total acids in wines. After treating the wine with a cation-exchange resin, oxalic acid can be precipitated as its calcium salt and titrated with potassium permanganate. For determination of tartaric acid in wine the acid can be precipitated as calcium tartrate or potassium hydrogentartrate.

Colorimetric methods are used for the determination of lactic and tartaric acids in wines. In the determination of lactic acid the procedure consists of the conversion of lactic acid into acetaldehyde by heating in the presence of sulfuric acid or by oxidation with cerium(IV) sulfate and subsequent formation of a colored compound with *p*-hydroxydiphenyl or piperidine and sodium nitroprusside. The red color formed is measured at 560–570 nm.

In the determination of tartaric acid in wines, the tartaric acid produces a colored complex with ammonium metavanadate, which is measured at 530 nm.

Major acids in distilled alcohol beverages are usually analyzed by high-performance liquid chromatography (HPLC). Several methods based on LC have been developed allowing simultaneous determination in alcoholic beverages of citric, tartaric, malic, succinic, lactic, and acetic acids in a single run using cation-exchange or C18 columns and refractive index, UV, or electrochemical detectors. If a previous step for cleaning or concentration is required, SPE based on a strong anion-exchange is the most selective technique for the enrichment of the ionizable acid analytes. It is preferred instead of the conventional solvent extraction method, which is time consuming and uses relatively large volumes of solvents.

Methods for the determination of organic acids by GC consist of direct and derivative techniques. The methods of extraction can take advantage of the acid properties of the acids by using an anion-exchange resin, or they can use a more unspecific strategy carrying out the extraction with an apolar solvent or resin. In the latter case, the pH of the beverage must

be adjusted to 7 to assure complete recovery of the acids from the aqueous phase.

With modern capillary columns derivatization of low molecular weight acids is not compulsory and peaks without tailing can be obtained. In this case, it is important to keep a permanent check on the inertness of the whole GC system, because acids are very sensitive to active sites on the column. However, to analyze heavier and more polar acids by GC, derivatization must be applied. Derivative methods involve the isolation of the acids from the matrix and afterward the conversion of the acids into the more volatile benzyl or trimethylsilyl esters.

A recent alternative to HPLC or GC in the analysis of organic acids is capillary zone electrophoresis. It provides completely different selectivities from chromatographic methods, shorter analysis times, and no derivatization is required. As a drawback, the lack of UV absorbance of aliphatic organic acids above 220 nm requires the addition of substances showing strong UV absorption for indirect UV detection.

## Esters

The esters of aliphatic monocarboxylic acids are the most numerous of the neutral volatile aroma compounds in alcoholic beverages. Because of the relatively high volatility of the esters it has often been proposed that esters have a noticeable influence on the odor of a beverage.

Esters of aliphatic di- and tribasic carboxylic acids occur frequently as aroma components in alcoholic beverages. Because these compounds are mildly odored, they are apparently not very significant aroma factors. In addition to aliphatic fatty acid esters, several hydroxyl- and oxo-acid esters have been determined by GC/MS. Unlike the fatty acid esters, the esters of hydroxyl and oxo acids are slightly volatile compounds. However, they do not play an important role in the formation of the odor.

Titrimetric and colorimetric methods are two classical methods for determining the ester contents of alcoholic beverages. The titrimetric procedure involves the treatment of esters with an excess of base followed by determination of the quantity of base required to hydrolyze the esters present in the sample. The colorimetric procedure involves the esters reacting with hydroxylamine in an alkaline solution to form a hydroxamic acid, which forms a colored complex with iron(III).

It becomes clear that these chemical methods are too long and not specific, and are very rarely used today; instead, analysts prefer to use GC-based procedures. GC has many advantages over the classical

methods. The direct method of GC can give good reproducibility and enough sensitivity, especially when large volume injection can be performed. But regular direct injections of alcoholic beverages accumulate nonvolatile material in the injection port, leading to losses in chromatographic performance, appreciable after a few injections in the cases of wine and beer.

In most investigations, however, procedures for isolation and enrichment are required. Generally, liquid-liquid extraction with a high sample/solvent ratio is used prior to GC analysis. Among the solvents used are Freon 113, isooctane, ether, pentane, and dichloromethane. Enrichments of  $\sim 20$  times of the original sample are enough to quantify a few milligrams per liter of the esters using splitless injection and FID detection. Many other procedures have been widely applied including distillation and headspace analysis but currently SPE and SPME are the techniques of choice for the possibility of automation and because of the low volumes of solvents used.

Summarizing, volatile compounds with concentrations  $\sim 0.1 \text{ mg l}^{-1}$ , including major esters and higher alcohols acetates, can be determined after a single isolation step and GC-FID detection. Some minor esters, at concentrations between  $0.1 \mu\text{g l}^{-1}$  and  $0.1 \text{ mg l}^{-1}$  will require a powerful isolation-preconcentration step and further GC-MS analysis.

## Other Important Volatile Compounds

There is an important part of the aroma of beverages elicited by compounds that present very serious analytical problems. This is a heterogeneous group formed by compounds whose analysis is very difficult due to different reasons, such as bad chromatographic behavior and poor chemical stability, extremely low concentrations, or very poor analytical properties. Volatile sulfur compounds, alkyl methoxy-pyrazines, furaneol, sotolon, and some aromatic thiols are well-known examples of this group. In general, the analysis of these compounds requires the development of specific methods of isolation, or detection, or the use of chemical derivatives. Currently, a great effort is devoted to developing new analytical methods to characterize these flavor components, among them GC-olfactometry is a useful choice.

### Introduction

The European Union (EU) directive 1493 (1999) defines wine as a product obtained exclusively from the total or partial alcoholic fermentation of crushed or intact fresh grapes or grape musts. During the process of vinification, grapes undergo two types of transformation:

1. The alcoholic fermentation whereby fermentable sugars (glucose and fructose) are converted into ethanol by the anaerobic action of yeast:

This reaction also produces  $25.4 \text{ kcal mol}^{-1}$  of energy that heats the mass in fermentation. The must contains between 150 and  $250 \text{ g l}^{-1}$  of sugar, which in the case of dry wines drops to less than  $2 \text{ g l}^{-1}$  when fermentation is completed after 4–10 days. If the fermentation is deliberately stopped, for example, by the addition of ethanol or sulfur dioxide, the resulting sweet wine will contain residual sugars of up to  $60 \text{ g l}^{-1}$  and an alcohol content slightly higher than that of a dry wine (15–17 vol.%).

2. The malolactic fermentation (MLF), where as a result of bacterial action malic acid is converted into lactic acid. This process is not, in reality, a ‘fermentation’ process, rather a biochemical process involving the removal of one of the carboxylic acid groups of malic acid by the action of bacteria of the *Pediococcus*, *Leucomastoc*, and *Lactobacillus* genera. Since the MLF reduces the acidity of a wine, it is a process that is encouraged in red wines and frequently prevented (by the addition of sulfur dioxide) in white and rosé wines in order to preserve the perception of freshness on the palate.

The analysis of a wine at all stages of its production is essential to ensure both the quality of the product from the consumer's point of view, and to establish that it conforms to the legislative requirements. It is for this reason that a series of analyses are routinely carried out – some on the wine during production, some on the finished product, and some on both. In both cases, chemical analyses are frequently complemented

by organoleptic analyses (tasting), though this aspect of wine analysis will not be treated here.

A compendium of analytical methods for wines, musts, and products used in wine technology was first published by the international wine organization (OIV: Organisation internationale de la vigne et du vin) in 1962. The compendium is updated on a yearly basis and most recent edition (see Further Reading) contains in excess of 70 monographs. The OIV works in close association with the European commission (EC) and in several cases where an EC method does not exist for a particular analysis it is recommended the recognized methods of the OIV be used.

In September 2000, the OIV adopted the system of method classification used by the Codex Alimentarius Commission for Method of Analysis and Sampling. In this system, methods of analysis are classified into four groups as follows:

**Category I (Criterion benchmark method):** This type of method determines a value that can be arrived at only by that method *per se* and which by definition serves as the only method for establishing the accepted value of the parameter measured.

**Category II (Benchmark method):** A category II method is designated as the benchmark method in cases where category I methods cannot be used. It should be selected from category III methods (as defined below). Such methods should be recommended for use in cases of disputes and for calibration purposes.

Categories I and II are reference methods that provide the most accurate results. They are used in case of litigation in international transactions, and should be employed for standard reference materials intended for subsequent standardization of other (nonreference) methods.

**Category III (approved alternative methods):** A category III method meets all the criteria specified by the Sub-Committee on Methods of Analysis and is used for monitoring, inspection, and regulatory purposes (e.g., enzymatic determinations of glucose and fructose).

**Category IV (auxiliary method):** A category IV method is a conventional (usual) or recently implemented technique for which the Sub-Committee on Methods of Analysis has not yet specified the requisite criteria (e.g., synthesized coloring agents, measurement of oxidation–reduction potential).

Only methods that have been adopted since September 2000 have been classified in this manner; existing analytical methods are still classified by the old

system (reference, usual, and rapid test methods). Since the analyses described in this article have not yet been re-classified by the OIV, they will, where appropriate, be referred to as simply 'reference' or 'usual' methods.

The analyses that are routinely carried out in wine are alcohol content (vol.%), sugars ( $\text{g l}^{-1}$ ), glucose and fructose ( $\text{g l}^{-1}$ ), glycerol ( $\text{g l}^{-1}$ ,  $\text{mg l}^{-1}$ ), pH, total acidity ( $\text{meq l}^{-1}$ ), lactic, malic, and tartaric acids, volatile acidity ( $\text{meq l}^{-1}$ ), malvidol diglucoside, and polyphenols. The total and free sulfur dioxide content is also routinely analyzed in wine; however, since it is not a native constituent of wine its analysis will not be described in this article.

## Alcohol

Next to water, alcohol is the most abundant constituent of wine. It is estimated that it was first analyzed by Arnauld de Villeneuve in Montpellier in the early part of the fourteenth century, though the notion of alcoholic strength in terms of degrees of alcohol was first proposed by Gay-Lussac some 200 years ago, a concept that has changed little in the intervening period. The alcohol content is usually expressed in terms of percentage volume (vol.%), specifically the number of liters of ethyl alcohol contained in 100 l of the product, measured at  $20^{\circ}\text{C}$ . The number of grams per liter of ethanol in the product are obtained by multiplying the vol.% by  $0.78924 \text{ g ml}^{-1}$ . There are various reasons for analyzing the alcohol content of wine. The first is to ensure that a wine conforms to legislative criteria currently in force. According to the EU directive 1493 (1999), a wine may only be classified as such if it contains a minimum amount of alcohol, which varies from 6% to 10% volume depending on the climatic production zone and whether the must has been enriched with grape or beet sugar. Dry wines may not contain more than 15% alcohol by volume and wines originating in countries outside the EU for sale within the Union must contain not less than 9% and not more than 15% alcohol by volume. Secondly, since alcoholic beverages are subject to taxes and duty that depend on the alcohol content, the accurate determination of this parameter will have significant commercial implications, especially for transactions involving large volumes of wine.

There are a variety of methods in which the alcohol content of a wine may be determined, which may be as **Table 1** shows, loosely divided into direct and indirect methods. The latter involves prior separation of the alcohol by distillation, usually by steam distillation, whereas the direct methods may be carried out on wine without any sample pretreatment. Within both categories there exist both physical, and less widely used, chemical methods.

**Table 1** Methods used for the determination of alcohol

	<i>Physical</i>	<i>Chemical</i>
Indirect (distillation)	Hydrometry  Pycnometry Hydrostatic balance Paar densitometer Refractometry	
Direct	Ebullimetry  NIR reflectance Heat of reaction (ethanol- $\text{K}_2\text{SO}_4$ ) Gas chromatography Direct Headspace Liquid chromatography	Enzymatic (biosensors)

### Indirect Methods

Distillation/pycnometry is a type I method for determination of alcoholic strength; it is used for labeling discrepancies and dispute resolution, since if correctly executed it gives a highly accurate result (to within 0.03 vol.%). The wine is steam distilled to collect the alcohol fraction with measures taken to avoid collecting other volatile substances. The distillate is then transferred to a glass recipient (a pycnometer – **Figure 1**) and weighed to four decimal places. The density of the distillate is calculated from the weight of the distillate and the alcoholic strength is then calculated from a series of tables (in the OIV compendium) relating the density to the vol.% at different temperatures. This method gives highly accurate results and does not require a standard but is time consuming, requires the availability of an accurate balance, and highly trained personnel.

Distillation/hydrometry is less time consuming, less cumbersome, and less expensive than distillation/pycnometry, but it yields less accurate results, in the order of 0.1 vol.%. Furthermore, it tends to give lower results and the hydrometer must be kept extremely clean, as any material adhering to it will falsify the results. The hydrostatic balance (which is also an OIV type I method) is based both on gravimetry and the principle of Archimedes: a plunger attached to a balance is totally immersed in the liquid (the distillate for wine alcohol analysis). The volume of the displaced liquid is constant; its density, obtained simply by weighing, is directly converted in automated instruments to alcoholic strength. Refractometry, also an OIV 'usual' method is much less widely used. Measurements of the

**Figure 1** A pycnometer and its matching tare. A, lateral capillary tube; B, dilation chamber; C, ground glass neck; and D, thermometer.

distillate are made using a refractometer capable of reading refraction indices between 1.330 and 1.346. The temperature is recorded, the index of refraction at ambient temperature is converted to its equivalent value at 20°C, and the alcoholic strength is read from appropriate conversion tables. The vibrating tube density detector is an OIV type I method and is extremely and widely used. It consists of a U-shaped tube that creates mechanical resonant vibrations within the liquid it contains. The square of the resonance frequency is inversely proportional to the density, which can be determined in a single measurement and is directly converted into alcohol content in automated devices.

### Direct Methods

Alcoholic strength analysis by near-infrared reflectance. This technology is extremely and widely used and is the industry standard for both larger wineries and for commercial oenological laboratories. This fast and accurate method of measuring alcoholic strength is calibrated using distillation/pycnometry.

Enzymatic methods for alcohol determination frequently rely on the activity of alcohol oxidase alone or combined with horseradish peroxidase alcohol, quinoxinoprotein alcohol dehydrogenase, or pyrroloquinoline quinine-dependent dehydrogenases. The enzymes are usually incorporated into biosensors for automated and routine application. The reaction may be followed by monitoring the concentration of either NADH or hydrogen peroxide produced in the reaction. The concentration of NADH is determined by its ultraviolet (UV) absorbance at 340 nm, and amperometric or

chemiluminescence detection is used to measure the hydrogen peroxide produced.

In order to automate the analysis, these methods frequently combine immobilized enzymes with flow or sequential injection techniques. These methods may include a separation step such as solid-phase extraction, gas diffusion, or pervaporation. The latter is a nonchromatographic separation technique, which selectively separates a liquid mixture by partial vaporization through a nonporous polymeric membrane. Separation is not based on relative volatilities as in distillation, but rather on the relative rates of permeation through the membrane.

The advantage of enzyme-based methods is that they are highly specific – methanol and higher alcohols are not detected; however, as previously stated, these compounds are present in such minor quantities compared to ethanol that the accuracy of the result is not significantly improved. On the other hand, since enzymatic methods are highly sensitive, dilution factors ranging from 50 to 1000 are required, which may lead to significant error in the final determination. For this reason, also due to the fact that these methods are costly, the majority of oenological laboratories do not use enzymatic methods to analyze ethanol in wine.

High-performance liquid chromatography (HPLC) may be used for the simultaneous separation of ethanol and other wine constituents such as carbohydrates, glucose, fructose, and saccharose, coupled with either refractive index or Fourier transform infrared (FTIR) detection. Ethanol may also be code-terminated with other volatile compounds in wine by gas chromatography with flame ionization detection. It is important to note that chromatographic methods for the analysis of ethanol are not suitable where accurate determinations are required.

### Sugars

In a dry wine, the concentration of residual sugars, i.e., the amount of sugar remaining after the completion of the alcoholic fermentation, is in the region of 0.3–3 g l<sup>-1</sup>. Above this concentration there is a risk that bacteria such as *Leuconostoc oenos* (one of the bacteria involved in the malolactic fermentation) will degrade the sugars leading eventually to the formation of acetic acid and thus spoilage of the wine. For that reason the criteria of the Appellation Contrôlée system in France require that a dry wine does not contain more than 2 g l<sup>-1</sup> of (reducing) sugars and why wines that contain significantly more than this are frequently sterilized by filtration or pasteurization before bottling.

### Total Reducing Sugars

For the reason outlined above, the analysis of residual sugar forms part of the routine analysis of wine. The OIV reference method involves a redox reaction that determines the total reducing sugar content (composed primarily of glucose and fructose). The method requires a sample preparation step to eliminate other reducing compounds such as polyphenols and uronic acids. The wine is neutralized, dealcoholized, and applied to an anion-exchange column, which fixes the uronic acids. The eluate is then treated with a mixture of lead acetate and calcium carbonate to precipitate the tannins. The mixture is filtered and the filtrate is then analyzed by redox titration by the Luff method. This analysis is precise but requires a certain level of skill and extreme attention must be paid to factors such as the reaction time and dilutions in the case of sugar-rich wines.

To obtain an estimate of the quantity of sugar in wine, it is possible to use a proprietary method (Clinitest<sup>®</sup> AMES) that was originally designed to measure sugar in urine. The method, also based on the reducing properties of the sugars, involves reacting a small volume of wine with a Clinitest tablet and comparing the color obtained with a scale provided by the manufacturer. It is necessary to modify the scale as follows in order to apply it to wines:

AMES values	0	0.25	5	7.5	10	20	g l <sup>-1</sup>
Modified values	1	2	3	5			g l <sup>-1</sup>

This method is useful for distinguishing wines in which the alcoholic fermentation has finished and those that yet contain several g l<sup>-1</sup> of sugar; for accurate analyses alternative methods should be used. Its advantages of low cost and simplicity of use, however, render it accessible to even the smallest wineries.

Automated or semiautomated versions of classic chemical reactions for sugars (e.g., Fehlings solution, picric acid potassium hexacyanoferrate(III)) are also used. A so-called UV/UV system was recently described to follow the evolution of sugar concentration during winemaking, but which may also be applied to finished wines. The principle of this system is that the sugars are converted by exposure to UV light at 254 nm into UV-absorbing aldehydes and ketones characterized by a peak at ~268 nm. Interference by ethanol in the analysis is removed by dilution of the sample.

### Determination of Individual Sugars

The OIV compendium describes enzymatic individual methods for the determination of glucose and fructose. These methods are based on the conversion

of glucose-6 phosphate (G6P) to gluconate-6-phosphate in the presence of G6P dehydrogenase. The concomitant reduction of NAD to NADH (related to the concentration of G6P) is measured spectrophotometrically at 340 nm. Fructose-6-phosphate is converted to G6P by hexokinase before reaction of G6P dehydrogenase. Sensor-based enzymatic methods for the determination of sugars have also been described, usually involving immobilized glucose oxidase or pyrroloquinoline quinone dependent (oxygen independent) glucose dehydrogenase.

Individual sugars can also be measured by separation techniques such as liquid chromatography (LC) and capillary electrophoresis (CE). Separations are usually ion-exchange based with refractive index detection. With this type of method it is also possible to determine simultaneously other wine constituents such as carboxylic acids, sugars, glycerol, and ethanol in wines. Different detection modes may be used in conjunction with postcolumn derivatization or alternatively the eluate may be directly analyzed by FTIR.

### Acids and Acidity

Wine is one of the most acidic alcoholic beverages with pH values ranging from 2.8 to 3.8; white and rosé wines are, in general, more acidic than red wines due to the natural desacidification brought about by the MLF (see Introduction). It is also possible to adjust the pH of a wine, a procedure that may be required for technological reasons or to protect against bacterial growth. Tartaric acid (the most abundant acid in grapes and wines) is normally used for acidification, whereas desacidification – a more unusual and delicate procedure – involves the addition of either potassium tartrate, or calcium or potassium hydrogen carbonate.

The acidity of a wine encompasses a number of parameters

1. pH,
2. Individual wine acids,
3. Total acidity, and
4. Volatile acidity.

Since the measurement of pH is a standard procedure, it will not be treated here. The other three parameters will each be discussed in turn.

### Total Acidity

The total or titratable acidity of a wine is defined as the fraction of nonionized acids in the wine; officially, it is determined by the volume of sodium hydroxide required to bring the pH of a specified

volume of wine to 7. This means, of course, that a proportion of the acids will not be neutralized (as the vast majority of the acids involved are weak acids); however, it would be impossible to determine the true endpoint of the titration given the variety of acids (and thus  $pK_a$ s) in question. The OIV methods for the determination of total acidity use 10 ml of wine; a solution of  $0.1 \text{ mol l}^{-1}$  sodium hydroxide and the titration is effected either by pH measurement (reference method) or with bromthymol blue indicator (usual method). The results are expressed in  $\text{meq l}^{-1}$  (titer volume  $\times 10$ ), in terms of  $\text{g l}^{-1}$  tartaric acid (titer volume  $\times 0.75$ ), or more usually in terms of  $\text{g l}^{-1}$  sulfuric acid (titer volume  $\times 0.49$ ). Common values are in the region of  $60\text{--}70 \text{ meq l}^{-1}$ . Since carbon dioxide is not considered as part of the total acidity, it is first removed from the wine by agitation under vacuum.

### Volatile Acidity

The volatile acidity is a test of the state of health of a wine. This is because it is represented principally by acetic acid that may be formed by the oxidation of ethanol by *Mycoderma acetii*, the degradation of tartaric acid by *Lactobacillus plantarum* (reaction [I]) or by the degradation of citric acid by *Leuconostoc oenos* of (reaction [II]).

[I]

Acetic acid then combines with ethanol to form ethyl ethanoate, which contributes to the pungency perceived wines with high volatile acidity.

Although limits are imposed for the amount of this acid in a wine (OIV:  $20 \text{ meq l}^{-1}$ ) it is a significant increase in the concentration of acetic acid (rather than its absolute value) during the course of vinification or aging that signals a problem with the wine. In order to correctly determine the concentration in volatile acidity, it is necessary to eliminate  $\text{CO}_2$  and subtract the concentration of various antiseptics or preservatives that may have been added, i.e., sulfur dioxide, sorbic acid, salicylic acid, and sodium salicylate. Volatile acidity is expressed in terms of

$\text{meq l}^{-1}$ , or in terms of  $\text{g l}^{-1}$  sulfuric acid, or more frequently acetic acid. The method involves steam distillation since 100% recovery of acetic acid would not be possible with direct distillation.

### Individual Organic Wine Acids

The acids present in a given wine are determined by the grape variety, climate, presence of gray rot (*Botrytis cinerea*), yeasts, bacteria, and various treatments to which the wine may be subjected (sulfur dioxide, ascorbic acid, acidification, desacidification). There are at least 50 different acids in wine ranging in concentration from 1 or  $2 \text{ g l}^{-1}$  (tartaric, malic, succinic acids) to hundreds of  $\text{mg l}^{-1}$  (citric, lactic, acetic acids) to tens of  $\text{mg l}^{-1}$  (pyruvic, shikimic acids). However, tartaric, malic (depending on the MLF), acetic, and succinic acids constitute 80–90% of total complement of wine acids.

Simultaneous determination of individual organic wine acids may be obtained by either LC or CE. In the case of the former, either reversed-phase liquid chromatography (RPLC) or ion-exchange chromatography may be used if only the principal organic acids are to be determined; a combination of both chromatographic modes may be necessary if the lesser organic acids, such as shikimic acid, are to be analyzed simultaneously. In either case, the mobile phase consists of a dilute aqueous acidic solution; even in RPLC no organic modifier is added due to the polarity of the organic acids. Various detection methods are employed, for example, direct UV detection at 254 nm in the case of HPLC, indirect UV in CE, and conductimetric or refractive index detection with ion-exchange chromatography. Some methods do

not require sample preparation but greater sensitivity and selectivity is obtained if the wine is first passed through a reversed-phase solid-phase extraction cartridge to remove interfering compounds such as sugars, polyphenols, and anthocyanins. The OIV compendium gives an HPLC method for the simultaneous determination of citric, lactic, and acetic acids (strong ion-exchange chromatography) or tartaric, malic, malic shikimic, succinic, and fumaric acids (reversed-phase chromatography). In the latter case, it is necessary to use two 25 cm (octadecylsiloxane-bonded silica) columns in series. Detection in both cases is at 210 nm and sample cleanup is by solid-phase extraction.

Chemical methods also exist for the various organic wine acids. For tartaric acid, the OIV describes a method involving sample cleanup on an ion-exchange column followed by reaction between tartaric acid and vanadic acid to give a red complex that is measured spectrophotometrically. This reaction may be incorporated into a flow injection system, which eliminates the need for the ion-exchange sample cleanup step. Lactic acid is first oxidized to ethanol and measured by colorimetry following reaction with nitroprusside and piperidine; for citric acid the chemical method requires controlled oxidation to form acetone which is subsequently separated by distillation and determined by iodometric titration.

Enzymatic methods rely on similar principles: redox reactions involving the acids associated with either the oxidation of NADH or the reduction of NAD. The reaction is followed by the appearance or disappearance of NADH, which is measured spectrophotometrically at 340 nm. The primary reaction with the acid is often coupled to a second reaction in order to remove the product and thus drive the reaction equilibria to completion. Some of the possible reactions are summarized in the following schemes:

#### Lactate

LDH: lactate dehydrogenase (L-LDH for L-lactate and for the conversion of pyruvate; D-LDH for D-lactate).

#### Citrate

CL: citrate lyase; MDH: malate dehydrogenase.

#### L-Malate

GOT: glutamate-oxaloacetate transaminase.

Paper chromatography is extensively used to follow the progress of the malolactic fermentation and the simplicity of this method is such that practically all wineries can carry it out. It is based on the difference in  $R_f$  values between malic and lactic acids using a mobile phase consisting of acetic acid and butanol. Bromothymol blue is incorporated into the mobile phase as indicator and thus the acids appear as yellow spots on a blue background. The absence of a spot for malic or lactic acid indicates that the MLF has or has not, respectively, taken place.

## Phenolic Compounds

The phenolic compounds are amongst the most important grape and wine constituents. They are responsible for all the differences in color and taste between red and white wines. They represent a diverse group of compounds for which a number of different classification systems have been applied.

Wine phenols are commonly referred to as 'polyphenols', due as may be seen in **Figure 2**, to the presence of multiple phenolic groups in their structures, which confer on these compounds various properties linked to health benefits, specifically the antioxidant properties attributed to the consumption of moderate amounts of red wine. Much has been published on this subject and the area and references to reviews may be found in 'Further reading' section.

The phenolic acids of wine (**Figure 2A**) consist principally of derivatives of benzoic and cinnamic acids. The cinnamic acids are extensively esterified with tartaric acid (e.g., caffeoyltartaric or caftaric acid) and they also form acylated derivatives of anthocyanin monoglycosides (see below). These compounds do not play a significant role in the organoleptic properties of wine, though caftaric acid is highly sensitive to oxidation, which turns the must or the wine brown. Bacterial action can lead to the conversion of cinnamic acid derivatives (principally *p*-coumaric and ferulic acids) into volatile phenols such as ethyl phenol, ethyl gaiacol, or vinyl gaiacol, which even in minor amounts lend intensely disagreeable aromas and flavor to the wine.

The flavonoids (**Figure 2B**) are yellow-colored pigments that give the pale yellow color to white wines. They are also present in red wines but their color is masked by the anthocyanins (**Figure 2C**), the coloring substances of red wines. Like the anthocyanins, the flavonoids exist primarily as heterosides where the 3-position on the heterocycle contains a sugar moiety. The latter may in turn be acylated with cinnamic acid, which confers greater stability on the molecule.

## (A) Phenolic acids

(i) Derivatives of *o*- and *p*-hydroxybenzoic acid

R = H	R' = OH	Catechic acid
R = OH	R' = OH	Gallic acid
R = OCH <sub>3</sub>	R' = OH	Vanillic acid

## (ii) Derivatives of cinnamic acid

R = H	Coumaric acid
R = OH	Caffeic acid
R = OCH <sub>3</sub>	Ferulic acid

## (B) Flavonoids

R <sub>1</sub>	R <sub>2</sub>	Aglycone
H	H	Kaempferol
OH	H	Quercetin
OH	OH	Myricetin

## (C) Anthocyanins

R <sub>1</sub>	R <sub>2</sub>	Aglycone
OH	H	Cyanidin
OCH <sub>3</sub>	H	Paeonidin
OH	OH	Delphinidin
OH	OCH <sub>3</sub>	Petunidin
OCH <sub>3</sub>	OCH <sub>3</sub>	Malvidine

## (D) Tannins

(+) Catechin 2R, 3S

(–) Catechin 2S, 3R

(+) Epicatechin 2S, 3S

(–) Epicatechin 2R, 3R

**Figure 2** Structure of phenolic compounds. (A) Phenolic acids: (i) derivatives of *o*- and *p*-hydroxybenzoic acid, (ii) derivatives of cinnamic acid; (B) flavonoids; (C) anthocyanins; and (D) Tannins.

The sugar moiety, which in wine anthocyanins is usually D-glucose, or more rarely L-rhamnose or D-galactose, occurs principally in the 3-position. Malvidne-3-glucoside is by far the most abundant of the anthocyanins in wine produced from *Vitis vinifera* varieties. It should be noted that certain hybrid species of *Vitis* (*Vitis vinifera* × *V. berlandieri* or *V. rupestris*) contain malvidne-3,5-diglucoside and these species

are not permitted in wines produced or intended for sale in the European Union on account of the elevated levels of methanol they produce during vinification. Identification of the presence of such a hybrid variety in a wine is by determination of the quantity of malvidine-3,5-diglucoside, an analysis that is rapidly carried out by thin-layer chromatography.

The tannins naturally occurring in wine are known as condensed tannins, polymeric structures resulting from the polymerization of elementary phenol compounds, polyhydroxyflavan-3-ols known as the catechins (**Figure 2D**). Depending on the configuration of the chiral carbons in positions 2 and 3 of the heterocycle, four different stereoisomers are possible, (+) and (–) catechin and (+) and (–) epicatechin; (+) catechin and (–) epicatechin are the principal building blocks of wine tannins; these monomers rapidly condense to form dimers, trimers, oligomers, and polymers during the course of vinification and wine aging. They also condense with anthocyanins, a process that during vinification is important in the stabilization of wine color. Unlike the flavonols, the pyran ring of the flavan-3-ols is saturated and non-planar and so these compounds have a maximum UV–visible absorbance at 280 nm, as opposed to ~370 and 520 nm for the flavonoids and the anthocyanins, respectively.

The methods employed for the determination of wine phenolic compounds are highly varied, given the diverse nature of their structure, polarity, hydrophobicity, and UV and visible-light absorption characteristics. It is possible to separate simultaneously the majority of the principal nonpolymerized wine phenolic compounds by HPLC or CE. In the case of the former, a reversed-phase column, usually octadecyl carbon (C18), is used. If the analysis is to include separations of the anthocyanins, the aqueous component of the mobile phase requires a pH of <2 (pH values as low as 1.5 have been used); either formic or acetic acids or a combination of both in concentrations ranging from 2% to 10% are used for this purpose. Above pH 2, severe peak broadening results from the slow interconversion between the various anthocyanin species leading to poor resolution and poor detection limits. In addition, the spectral properties of the anthocyanins are poor at pH values greater than 2 owing to the conversion of the flavylium cation to colorless carbinol pseudobase form (**Figure 3**). This means that chromatographic columns specifically designed to withstand extreme pH values are recommended for this analysis; in addition, peak tailing due to interaction between the hydroxyl groups of the polyphenols and unreacted silanol groups on the silica surface is minimized by using base-deactivated columns. The organic

**Figure 3** Different forms of anthocyanins.

component of the mobile phase is usually acetonitrile, though methanol is occasionally used. In order to achieve satisfactory separation of compounds of such diverse polarities, elaborate binary or even ternary gradients are required. Analysis time ranges from 50 to 120 min depending on the exact operating conditions and the degree of separation required. With a combination of judiciously chosen gradient and UV-visible photodiode array detection, it is possible to simultaneously analyze tannin monomers, dimers, and trimers ( $\lambda_{\max}$  280 nm), phenolic acids ( $\lambda_{\max}$  ~330 nm), flavonoids ( $\lambda_{\max}$  ~370 nm), and anthocyanins ( $\lambda_{\max}$  ~525 nm) in a single run. However, the presence of various combinations of these compounds, in varying concentrations, combined with the unavailability of many of the standards renders interpretation of the chromatograms rather difficult. Partially for this reason, mass spectrometry is more and more frequently used as a detection method for polyphenol analysis – atmospheric pressure-ionization techniques tend to be the most widely employed.

CE is not as widely used as LC for the analysis of wine polyphenols. As regards CE–UV analysis of the anthocyanins, separations must be carried out at very acidic pHs (due to the poor spectral properties of these compounds at neutral or basic pH values) and this presents problems in terms of method selectivity. CE is, on the other hand, better suited to the non-anthocyanin fraction of wine polyphenols.

As outlined earlier, a certain fraction of the wine polyphenols exist in condensed forms (tannin–tannin, anthocyanin–anthocyanin, tannin–anthocyanin), this fraction varying with the conditions of vinification and increasing with the age of the wine. For this reason, the above separation techniques remain relatively limited for the analysis of polyphenols given that only elementary nonpolymerized molecules, which play a relatively minor role in the overall properties of the polyphenols, may be determined. In order to analyze the condensed or polymerized fraction by one of these separation techniques it is necessary to carry out a thiolysis beforehand.

Except for specific applications, the requirements for routine polyphenol analysis can be adequately met by the application of a number of tests that are rapidly carried out without the need for elaborate instrumentation. It is difficult to determine or to express the results in terms of concentration, so therefore various indices are used that represent either total polyphenols or different groups of polyphenolic compounds. The tests briefly described below are useful in following the progress of a vinification, in making comparisons between different wines, and in seeking to quantify certain organoleptic properties of wines (notably bitterness and astringency).

The total polyphenol index is obtained by diluting the wine and measuring its absorbance at 280 nm. The index is given as the absorbance multiplied by the dilution factor (100 in the case of red wines). This test does not take into account the colorless chalcone forms of anthocyanins (**Figure 3**) nor the phenolic acids that absorb at 230 nm, though these compounds are present in such small quantities that they contribute little to the overall polyphenol content.

The permanganate index is based on the reduction of permanganate by the polyphenols using the indicator carmino indigo, the color of which varies between blue and yellow according to its oxidation state. The correct endpoint – when the polyphenols are oxidized but not the sugars – is difficult to identify, and furthermore the reproducibility of the method is poor between operators. Nonetheless, it is possible to classify wines according to their

permanganate index (milliequivalents of permanganate used in the titration) as follows:

Red press wine	100–150
Tannic red wine	75
Soft red wine	60
Rosé wine	27–35
White wine	1–15

The Folin–Ciocalteu (F–C) index is a more reliable indicator of polyphenol content and is extensively used. The reaction mixture consists of phosphotungstic and phosphomolybdic acids, which in alkaline medium, are reduced by the polyphenols to a mixture of blue oxides of tungsten and molybdenum, the absorbance of which is read at 750 nm. The F–C index is expressed as 100-fold the absorbance of the sample; typical values are in the region of 25–35.

There are number of chemical methods for the determination of the total anthocyanin content in a wine, the most simple being variations in the color of a wine as a function of pH. At very acidic pH, anthocyanins are in their flavinium cation form, whereas under mildly acidic conditions the carbinol pseudobase (**Figure 3**) is formed. The absorbance of the wine is read at pH 0.6 and at pH 3.5 and the difference in absorbance has been empirically shown to correlate with the anthocyanin concentration. Anthocyanin determination using the difference in absorbance before and after the addition of a known quantity of sulfur dioxide is based on the same principle.

It is also possible to fractionate wine anthocyanins on the basis of their degree of polymerization on a hand-packed column consisting of polyvinylpyrrolidone, silica gel G, and silica 60. The free anthocyanins elute in the first fraction (methanol–HCl 999:1), slightly polymerized anthocyanins in the second fraction (formic acid–water 1:1), and the condensed polymeric forms are eluted in 100% formic acid. The absorbance of the three fractions is read spectrophotometrically (538 nm for the first fraction and 525 nm for the second and third fractions) and their relative proportions may thus be calculated. This test is a very good indicator of the age of a wine: the younger the wine the higher the absorbance of the first fraction due to the presence of anthocyanin monomers; conversely, the absorbance of the third (polymerized) fraction will be greatest in older wines.

Quantitation of total tannin concentration is still carried out by methods based on the classic Bate-Smith reaction: heating in strong acid medium leads to the formation of carbocations, which in an oxidant medium forms cyanidin (an anthocyanin). The reaction mixture thus turns red (hence the old name

for the tannins – proanthocyanidins) and its absorbance is read at 550 nm. Later refinements of the original 1954 method led to the incorporation of further measures in the technique. Various empirically derived calculations based on the absorbance at 470, 520, 550, and 570 nm can give a reasonably accurate measure of the total tannin content of a wine. These measurements do not, however, distinguish between tannin monomers, oligomers, or polymers. Tannins produce a sensation of bitterness or astringency on the palate due to their interaction with proline-rich proteins and glycoproteins in saliva. The tannin molecules most active in this respect are those whose molecular mass is between 600 and 3500; tannins of greater molecular mass are too cumbersome to access the active sites of the proteins, and this explains why during wine ageing, as tannins become more polymerized amongst themselves or with anthocyanins, they appear less aggressive to the palate. Eventually, this polymerization leads to molecules that are sufficiently large to precipitate, explaining the deposit often seen in old wines. This principle of the reaction between tannins and proteins forms the basis of a test, known as the gelatine index, for the degree of astringency of a wine. A specified volume of wine is mixed with a solution of gelatin (MM 5000–30 000) and allowed to react for 3 days and centrifuged. The tannin concentration of the wine before and after reaction with gelatin is determined as described above, and the index is expressed in terms of the percentage difference. The higher the gelatin index the greater the concentration of ‘astringent’ tannins in the wine. This test correlates reasonably well with the degree of astringency perceived by expert tasters.

## Automated Methods

To conclude this article, it is important to state that, in general, commercial oenological laboratories are equipped with automated instrumentation that carry out the above analyses (and others besides) in a single step. The most widely used instrumental technique is based on FTIR analysis. The infrared spectrum of an organic solution such as wine presents complex absorption spectra characteristic of the different wine components. The Michelson interferometer, which is at heart of the FTIR method, is based on the division of a polychromatic band of infrared radiation into two beams which then follow different optical pathways; one beam traverses the sample cell directly, while the other is reflected on a mobile mirror before arriving at the sample cell. For each elemental wavelength arriving at the detector cell there will be a phase difference, which is continuously varied

by the changing position of the moveable mirror. The two out-of-phase signals of the same wavelength arriving at the detector results in an interference signal, the intensity of which depends on the magnitude of phase difference. This variation in signal intensity as a function of the phase difference is called an interferogram. Fourier transform is a mathematical procedure that enables the construction of an infrared spectrum on the basis of the interferogram. A typical FTIR instrument used in wine analysis measures spectra between 1000 and  $5000\text{ cm}^{-1}$  (10 000–2000 nm), which lies between the near- and mid-infrared. Once the spectrum for each of the components in the wine have been established, specific wavelengths (up to 15) are selected for their quantitation; the wavelengths selected are those that show the best correlation between absorption intensity and concentration for a given parameter. With 15 different wavelengths, up to 97% of the 'information' relating to a given parameter may be obtained. Based on the absorption intensity at specific wavelengths for the spectra of reference standards, a polynomial calibration model is calculated by a statistical method, the most commonly used of which is partial least squares.

The instrument must be calibrated using reference standards for each of the parameters that are to be analyzed, which is a fundamental step in assuring the quality of the future results. In order to calibrate the instrument correctly it is necessary to analyze a large number of reference standards containing each of the analytes at known concentrations; it is considered that up to 150 wines of the same type are needed to establish a good calibration. The concentration of each of the parameters in the reference standards should be determined by a reference method, such as the methods described in this article, and obviously the quality of the calibration is directly related to the accuracy of the results obtained by the reference method. With good quality calibrations, FTIR is capable of excellent repeatability and reproducibility, frequently superior to those obtained with official 'usual' methods and in some cases to official 'reference' methods. There is usually a good correlation between reference methods and FTIR analyses; however, if the wine contains a substance for which the instrument was not calibrated the results obtained will differ enormously from those obtained by a standard reference method for that substance.

The technique is remarkably simple in its execution and the sample to be analyzed does not require any particular sample pretreatment, though if the wine is turbid, clarification by centrifugation or filtration may be appropriate. If the concentration in carbon dioxide exceeds  $\sim 750\text{ mg l}^{-1}$  it is

recommended to remove it under vacuum or by ultrasonication to avoid degassing in the analysis circuit. The sample is aspirated by a sampling needle and transferred by a peristaltic pump into a chamber where the sample is heated to  $40^\circ\text{C}$ . After passage through a filter, the sample enters the measurement cell which is composed of fluorosilicate. A typical sample cycle is of the order of 30 s, automated instruments can therefore analyze up to 120 samples per hour.

In spite of its incontestable advantages, the method is subject to certain limitations. First, calibration is based on a sample population of wine bearing certain common characteristics, such as region of origin, sugar concentration, and acidity. This implies that a given calibration will not be valid for all types of wines (or musts); in other words, the matrix plays a major role, and parameters measured in matrices differing significantly from that used in the calibration will generate erroneous results. To combat this problem a calibration may be developed using several different wine matrices; however, this will degrade the analysis precision and so a compromise must be sought between robustness and precision if several types of wines are to be analyzed using the same calibration. Many oenological laboratories circumvent this problem by establishing specific calibrations for different 'types' of wines (dry wines, sweet wines, musts, etc.). Apart from the quality of the calibration, the absorption characteristics of the individual parameter are also determining factors. Some compounds that present highly specific absorption characteristics will be selectively determined whereas others – even though they may be present in high concentrations – will be less selectively determined and thus the sensitivity of their analysis will be compromised. As this is a macroanalytical method, precision drops dramatically at concentrations below  $100\text{ mg l}^{-1}$ . Although many laboratories routinely apply FTIR to the analysis of several wine analytes (alcohol, sugars, glucose, fructose, total acidity, major organic acids, total polyphenols, etc.) there are some parameters for which the method is either not adapted (e.g., mineral elements or compounds present in small concentrations, such as the antiseptic, sorbic acid) whereas other parameters are either extremely matrix-dependent (total sulfur dioxide) or yield results of unacceptable precision (free sulfur dioxide, volatile acidity). Automated analysis of these compounds may be accomplished by a multiparameter sequential analyzer, the basis of which is the UV-visible absorbance of the analytes following chemical (iron, copper) or enzymatic (malate, lactate, citrate) reaction with appropriate reagents.

## Meat and Meat Products

**M O’Keeffe**, The National Food Centre (Teagasc), Dublin, Republic of Ireland

## Introduction

The analysis of meat and meat products is a significant activity in the general area of food analysis since they represent an important and relatively expensive component of the diet. Characterization of meat through chemical analysis is of importance to meat buyers in the food processing industry and is the subject of a large amount of regulatory control in most countries. Analysis of meat products is of importance for the food processing industry in product development, quality control/assurance, and for nutritional labeling. In addition, meat products are covered by a range of regulatory requirements to which adherence can be checked by chemical analyses. This article describes the analyses used for meat and meat products, covering both major and minor constituents, and addresses the range of methods available for particular analytes.

## Major Analytes

Fresh or unprocessed meat is characterized normally by microbial tests, by measurement of physical attributes such as tenderness and color, and by ‘proximate’ analysis; that is, the proportions of the major constituents of moisture, protein, fat, and ash

(inorganic material) in the meat. In the case of carcass meat, other measurements such as pH and color are commonly made to give an indication of quality. Meat is often tested for its freshness through rancidity tests such as peroxide value and thiobarbituric acid (TBA) number, which give a measure of oxidative rancidity in the fat, and the free fatty acid value, which gives a measure of hydrolytic rancidity. Spoilage of meat can be measured through assay of the total volatile basic nitrogen (TVBN), which is related to protein breakdown.

In the case of comminuted meat (e.g., burgers), the purpose of analysis is to characterize the main constituents (moisture, protein, fat, ash) and also to determine to what extent it differs from the intact meat. For example, typical analyses applied to comminuted meat samples might include meat species identification and determination of collagen and carbohydrate content. As the meat products move further away from the original entire meat, a range of analyses is used to characterize the food, particularly assays for nonmeat proteins, for additives such as salts, and for preservatives. In the case of cured meat and cured meat products, the important analyses are for salt, nitrite and nitrate, and other additives such as sugars and phosphorus (polyphosphates).

Meat products, under regulations, are defined according to ‘meat content’ and this may be calculated from compositional data. The percentage ‘fat-free meat’ is calculated from the total nitrogen content (corrected for any nonmeat nitrogen) using nitrogen factors specific for meat of each species. ‘Meat content’ is calculated as the ‘fat-free meat’ plus the fat.

## Meat and Meat Products

**M O’Keeffe**, The National Food Centre (Teagasc), Dublin, Republic of Ireland

## Introduction

The analysis of meat and meat products is a significant activity in the general area of food analysis since they represent an important and relatively expensive component of the diet. Characterization of meat through chemical analysis is of importance to meat buyers in the food processing industry and is the subject of a large amount of regulatory control in most countries. Analysis of meat products is of importance for the food processing industry in product development, quality control/assurance, and for nutritional labeling. In addition, meat products are covered by a range of regulatory requirements to which adherence can be checked by chemical analyses. This article describes the analyses used for meat and meat products, covering both major and minor constituents, and addresses the range of methods available for particular analytes.

## Major Analytes

Fresh or unprocessed meat is characterized normally by microbial tests, by measurement of physical attributes such as tenderness and color, and by ‘proximate’ analysis; that is, the proportions of the major constituents of moisture, protein, fat, and ash

(inorganic material) in the meat. In the case of carcass meat, other measurements such as pH and color are commonly made to give an indication of quality. Meat is often tested for its freshness through rancidity tests such as peroxide value and thiobarbituric acid (TBA) number, which give a measure of oxidative rancidity in the fat, and the free fatty acid value, which gives a measure of hydrolytic rancidity. Spoilage of meat can be measured through assay of the total volatile basic nitrogen (TVBN), which is related to protein breakdown.

In the case of comminuted meat (e.g., burgers), the purpose of analysis is to characterize the main constituents (moisture, protein, fat, ash) and also to determine to what extent it differs from the intact meat. For example, typical analyses applied to comminuted meat samples might include meat species identification and determination of collagen and carbohydrate content. As the meat products move further away from the original entire meat, a range of analyses is used to characterize the food, particularly assays for nonmeat proteins, for additives such as salts, and for preservatives. In the case of cured meat and cured meat products, the important analyses are for salt, nitrite and nitrate, and other additives such as sugars and phosphorus (polyphosphates).

Meat products, under regulations, are defined according to ‘meat content’ and this may be calculated from compositional data. The percentage ‘fat-free meat’ is calculated from the total nitrogen content (corrected for any nonmeat nitrogen) using nitrogen factors specific for meat of each species. ‘Meat content’ is calculated as the ‘fat-free meat’ plus the fat.

Related analyses in the meat and meat products area are the analysis of curing brines and of special meat fractions such as mechanically recovered meat (MRM). Completing the list of analyses on meat and meat products are the mineral and vitamin assays used to characterize the nutritional status of these foods.

## Sampling and Preparation

Meat and other edible tissues of animals are difficult samples to analyze because of the nonuniformity and inherent instability of the sample. Because of the high water content ( $\geq 70\%$ ) of raw meat, meat samples are particularly prone to change either in storage or during preparation for analysis. This is more of a problem for raw meat than for meat products, which are often 'stabilized' by some of the constituents added to the meat or by the processing procedures (cooking, curing) used.

In the case of raw carcass meat, another problem is that of obtaining a representative sample. Because the muscles of the animal (the primal cuts) are irregular in shape and in fat content, samples for analysis must be clearly defined in terms of anatomical position. In the case of boxed beef, which is used in meat processing, it is important to have a sample representative of the total content, particularly in terms of lean and fat.

Samples of meat are taken either from defined locations, as multiple subsamples over the entire material, which are combined to form the analytical sample, or as a single sample after comminuting and mixing to ensure homogeneity. Preferably raw meat samples should be analyzed immediately but, if this is not possible, refrigerated or frozen storage is required to prevent (reduce) alteration to the sample.

Having defined the batch that is to be sampled, the sampling must be such as to ensure that the batch will be characterized adequately from the analyses. The number of samples to be taken from a batch depends on criteria such as the number of discrete units in the batch, the importance of the analyte, and the confidence required from the results. Since these are subjective or variable criteria, the number of samples is determined initially and then particular procedures of sampling are followed.

The sampling of meat and meat products is covered by an International Standard (ISO 3100-1: 1991). This standard gives general instructions and specifies procedures to be followed for taking primary samples and is intended primarily for commercial, rather than regulatory purposes. It distinguishes between units not exceeding 2 kg in weight, which

are treated as a sample, and carcasses or meat cuts exceeding 2 kg in weight, from which secondary samples of 0.5–1 kg may be taken. The above standard deals with issues such as the inertness of the containers and the integrity of closures and the necessity to store and transport samples at 0–2°C (for analyses to be completed within 24 h) or frozen (where longer storage is required). The standard also describes the use of seals and the information to be attached to the sample container label.

Before analysis, meat samples must be ground in a suitable mincer or bowl-cutter to produce a homogeneous sample. Connective tissue is a particularly difficult component of the meat sample to homogenize and this is of importance in collagen analysis. Suitable comminution of meat samples is specified as a mincer (meat chopper) plate size of 4 mm or less.

Equipment used for sample preparation must be dry and clean and may be cooled or chilled. Speedy sample preparation is required to reduce heating and consequent evaporation of water, which would affect the determination of moisture content. Blades must be sharp to achieve consistent and fast comminution. Samples (preferably well chilled or slightly frozen) may be prepared by passing through a meat chopper or mincer multiple ( $3 \times$ ) times, often using plates of decreasing size where the sample is very large. Often, quite small samples are received for analysis and a bottom-driven bowl cutter may be more appropriate.

In the case of meat products that are a composite (such as meat-filled pies), the analysis may require separation of the sample into its constituent parts, weighing of each part, and analysis as separate samples.

## Standard Methods

### Moisture

Moisture is determined by measuring the loss in weight of the sample on heating. A standard method (ISO 1442: 1997) used consists of drying a sample of 5–8 g, mixed with predried sand, to constant weight with 2 h periods in an oven at  $103 \pm 2^\circ\text{C}$ . Methods approved by the Association of Official Analytical Chemists (AOAC) for moisture include air-drying of a 2 g sample in a convection oven at 100–102°C for 16–18 h, at 125°C to constant weight, or under vacuum at 95–100°C. An alternative procedure for moisture determination is microwave drying; integrated systems exist consisting of an electronic balance and control microprocessor that can give results after a drying period of 3–5 min.

In all cases, moisture determination is based on recording the mass that evaporates from the sample

under strictly defined circumstances of temperature and time. It is possible in some samples (1) that components other than water may be lost by evaporation or (2) that incomplete removal of water may occur due to formation of a 'skin' on the surface of the sample. Moisture determination, therefore, requires close attention to the exact conditions used and maintenance of constant conditions for each analysis.

### Protein

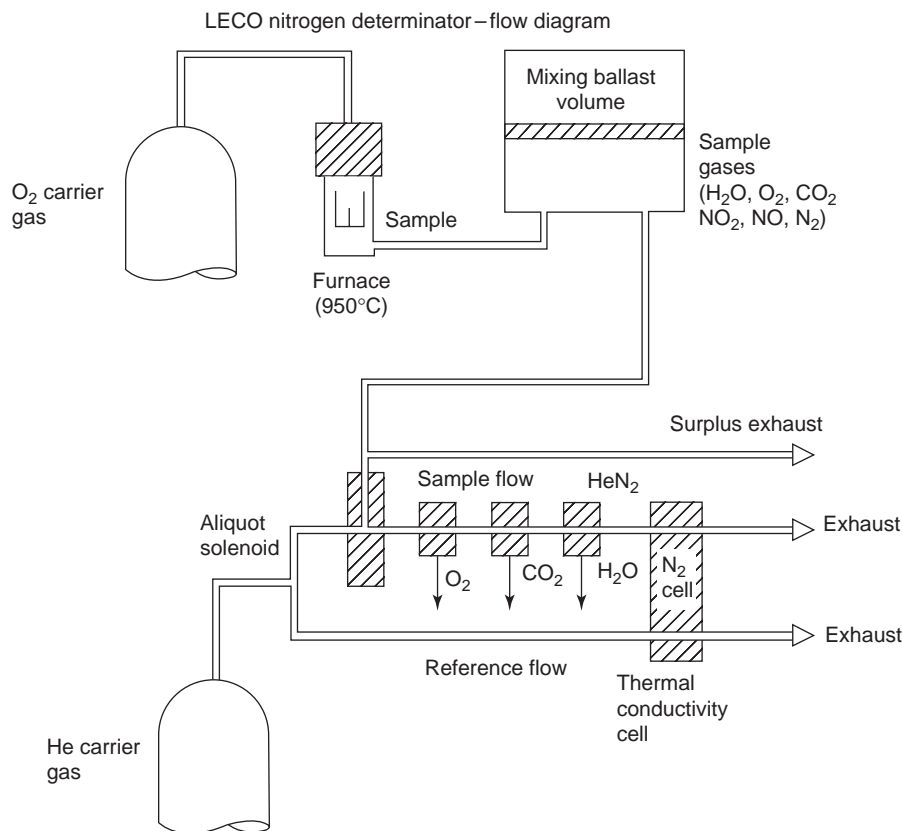

The total nitrogen content of the sample is determined after either reduction of all nitrogen to ammonia or liberation of all nitrogen as nitrogen gas. The 'crude protein' content of the sample is derived from the ammonia/nitrogen content by use of appropriate conversion factors. In the case of meat and meat products, the factor 6.25 is used to convert ammonia/nitrogen to crude protein, on the basis that 16% of protein is nitrogen.

Kjeldahl nitrogen is the classical assay for crude protein in meat, consisting essentially of a catalyst-aided (sulfate salts and copper or mercury) digestion with concentrated sulfuric acid at elevated

temperature, rendering of the resultant digest (containing ammonium sulfate) alkaline with concentrated sodium hydroxide, distillation of the liberated ammonia into an excess of acid, and back-titration with acid to determine the ammonia content. This ISO procedure (ISO 937: 1978) has been developed from a macrosystem in special flasks to a microsystem in tubes and in a variety of forms of automated and semiautomated systems – many of which are AOAC-approved methods.

An AOAC variation, still based on determination of ammonia, is an automated system of digestion with determination using the colorimetric reaction of ammonia with hypochlorite and phenol to produce an indophenol absorbing at 630 nm.

The Dumas method, based on determination of gaseous nitrogen in the sample, has been approved by the AOAC for crude protein in an automated form for a variety of foodstuffs. The modern versions of this system have fully automated sample introduction, combustion (950°C), removal of non-nitrogenous gases, and reduction of nitrogenous gases to nitrogen, and determination of nitrogen content by a thermal conductivity cell (Figure 1). The Dumas

**Figure 1** Crude protein determination by the Dumas method for total nitrogen with the 'LECO' apparatus. (Reproduced from O'Keeffe M (1992) *Chemical analysis of animal feed and human food*. In: Smyth MR (ed.) *Chemical Analysis in Complex Matrices*, pp. 241–287. Chichester: Ellis Horwood.)

**Table 1** Performance of Kjeldahl and Dumas methods for determination of protein in meat products (12 different laboratories, 30 different samples)

Performance measurement	Kjeldahl method	Dumas method
Repeatability ( $S_r$ )	0.11–0.40	0.12–0.41
Reproducibility ( $S_R$ )	0.29–0.49	0.18–0.46
Protein, overall mean ( $n=360$ )	15.59%	15.75%

From King-Brink M and Sebranek JG (1993) Combustion method for determining crude protein in meat and meat products. *JAOAC International* 76: 787–793.

method is attractive because it is a fully automated system, avoids use of corrosive and contaminant chemicals, and is a rapid method. However, the small sample size (<1 g) used in the Dumas method places critical requirements for homogeneity of sample that may not be as easily attained with meat samples as with other sample types. The Dumas method compares well with the Kjeldahl method both in terms of the performance criteria of repeatability and reproducibility and protein content determined, as shown from the results of an AOAC collaborative study among 12 different laboratories and using 30 different meat and meat product samples (Table 1). However, the Dumas method gives slightly higher protein values overall compared with the Kjeldahl method, which may be due to atmospheric nitrogen and/or additional nitrogen detected from basic amino acids. In samples with relatively low protein concentration (<30%), the difference between the two methods may not be of practical significance.

There may be a requirement to characterize the proteins in a meat product in terms of their amino acid content. This may be determined by hydrolysis with concentrated hydrochloric acid ( $6 \text{ mol l}^{-1}$ ) and separation and identification of the individual amino acids either (1) by ion exchange chromatography and colorimetric measurement using ninhydrin, or (2) by high-performance liquid chromatography of fluorescent derivatives of the amino acids.

## Fat

Standard methods for the determination of fat in meat and meat products are based on extraction of the fat from the sample using a lipophilic solvent and determination of the extracted fat by weighing or by measurement of specific gravity (relative density) changes in the extractant solvent. There are two ISO methods for fat in meat and meat products, one for 'free fat' (ISO 1444: 1996), which consists of repeated extraction of the sample with *n*-hexane or petroleum spirit in a Soxhlet apparatus, and the other for

'total fat' (ISO 1443: 1973), which involves an hydrolysis with hydrochloric acid prior to the solvent fat extraction. For some meat product samples, simple extraction of fat with solvent may be incomplete; digestion with hydrochloric acid liberates the fat by hydrolyzing proteins and carbohydrates. In both cases, the sample is oven-dried at  $103 \pm 2^\circ\text{C}$  prior to extraction with solvent. The fat content is determined by weighing the residue after evaporation of the solvent.

The primary AOAC method is a Soxhlet method, similar to the ISO 'free fat' method. An automated form of the Soxhlet petroleum spirit (petroleum ether) method is approved by the AOAC, using equipment such as the Soxtec<sup>TM</sup> apparatus. In this procedure, multiple samples, mixed with sand, are predried at  $125^\circ\text{C}$  (1 h) prior to a rapid solvent extraction step. There are two other AOAC-approved methods that are widely used for fat determination in meat and meat products. One method uses the Fosslet<sup>TM</sup> apparatus comprising a shaker or reactor that extracts the fat from the sample by very vigorous shaking in a metal container with perchloroethylene for 2–3 min. The specific gravity of the extract is measured in a magnetic float cell controlled by a potentiometer. The fat content can be determined from the difference in specific gravity between pure perchloroethylene and the extract. The second method is based on microwave-predrying of the sample, extraction of fat from the dried sample with dichloromethane in a custom-built extractor, and microwave-drying of the residue prior to weighing the extracted fat.

Both the Fosslet and the microwave systems are relatively rapid, a complete procedure taking not more than 10–15 min. Both these methods are very attractive for situations where rapid analyses are required, such as online for product control. However, where large batches of samples are to be analyzed and where results are not required within 24 h, the Soxhlet solvent extraction, or the more rapid Soxtec<sup>TM</sup> system, may be preferable. These latter techniques do not require constant attention, as is the case for the rapid methods. Good comparison between results obtained by Soxhlet extraction and the Fosslet technique has been reported. In the case of the microwave-based system, adjustment factors have been defined for different classes of meat products to overcome a negative bias in the method.

Supercritical fluid extraction (SFE) has been applied also for determination of fat in meat and meat products. Supercritical carbon dioxide, produced using elevated pressure (7.4 MPa) and temperature ( $31^\circ\text{C}$ ), extracts the fat from samples that have been mixed with moisture-absorbing agents, such as

diatomaceous earth. The advantage of this technique is that there is no waste solvent disposal problem and a number of samples may be extracted simultaneously. A number of studies have shown good agreement between the SFE and the Soxhlet methods.

X-ray absorption technology (e.g., Anyl-Ray<sup>TM</sup>) is used in the meat industry to determine indirectly the fat content of meat. The meat sample (~7 kg) is transilluminated with X-rays and the absorption of energy is related to the mineral content of the sample. Fat content is calculated from the relationship between fat, protein, water, and mineral content of meat.

Where the fat in a meat or meat product sample is to be characterized in terms of the fatty acid profile, extraction of the fat with chloroform/methanol is required. This solvent mixture, while it may not give complete fat extraction, is used to ensure no chemical change to the lipids and the extraction of phospholipids. Fatty acid analysis of the extracted fat is undertaken by formation of volatile methyl esters of the fatty acids (ISO 5509: 2000) and determination by gas chromatography (ISO 5508: 1990).

### Ash

Ash is the residue remaining after incineration of the sample in a furnace at temperatures in excess of 500°C. The AOAC method specifies drying of the sample and charring before ignition at 525°C. The ISO method (ISO 936: 1998) specifies incineration of the sample at  $550 \pm 25^\circ\text{C}$ , in a muffle furnace, following drying and carbonization of the sample either (1) separately in an oven and on a hot-plate or (2) in the furnace by gradually raising the temperature. In all cases, the ash is determined by weighing of the residue and care must be taken in handling the silica dishes to avoid losses.

A common practice is to determine ash content on samples that have been oven-dried for moisture determination. While ash may be used for determination of metals, salts, etc., attention must be given to the possibility of losses due to volatility of these components of the sample at the very high ashing temperatures used.

### pH

The pH of meat is an important measure of quality, a higher than normal pH (>pH 6.2 at 24 h after slaughter) or a lower than normal pH (<pH 5.9 at 45 min after slaughter) indicating conditions known as DFD (dark, firm, dry) and PSE (pale, soft, exudative) meat, respectively. The determination of such meat is important as the uses to which it can be put are limited. Such pH measurements are made on the carcass with a spear probe.

For laboratory measurements, an ISO method for pH (ISO 2917: 1999) specifies either homogenization of the sample in potassium chloride solution and insertion of the electrode(s) into the extract, or introduction of the electrode into prepared holes in the nonhomogenized sample. Other methods specify preparation of a slurry of the ground sample with an equal weight of water, or preparation of a homogenate in the ratio of one part meat to five parts sodium iodoacetate ( $5 \text{ mmol l}^{-1}$ )/potassium chloride ( $150 \text{ mmol l}^{-1}$ ).

### Collagen

Determination of the collagen content of meat products is important in controlling the eating quality (toughness) and for ensuring that too high an amount of low-grade meat, with a high level of connective tissue, is not in a product. Collagen content is determined from an analysis for the amino acid L-hydroxyproline, which occurs at much higher levels in collagen than in other muscle proteins.

The ISO method for L-hydroxyproline (ISO 3496: 1994) involves hydrolysis of the sample with sulfuric acid, at  $105^\circ\text{C}$  for 16 h. After filtration and dilution of the hydrolysate, the L-hydroxyproline content is determined by oxidation with chloramine-T and reaction with *p*-dimethylaminobenzaldehyde to form a colored complex that is measured spectrophotometrically at 558 nm. This method requires close attention to detail, particularly the color reaction which must be carried out under exact temperature and time conditions ( $60 \pm 0.5^\circ\text{C}$  for 20 min). The repeatability of the determination is assured by preparation of a calibration graph with each batch of samples. Using a specific microwave oven for digestion can reduce the time for this procedure to 30 min, so that the total time for analysis can take less than 3 h.

The collagen content is determined by multiplication of the L-hydroxyproline result by a factor of 8 (corresponding to the hydroxyproline content of collagen being equal to 12.5%, where the nitrogen-to-protein factor is 6.25).

### Additives

In the production of meat products, additives such as salts, sugars, and preservatives are used. Analyses for these substances are important in that maximum levels allowed in foods are specified in various national regulations such as the US Food and Drugs Administration and the European Commission DG SANCO.

The standard methods for sodium chloride in meat products are titrimetric methods in which the salt is extracted from the sample, reacted with excess silver

nitrate to form a silver chloride precipitate, and the residual silver nitrate titrated with thiocyanate. The ISO method (ISO 1841-1: 1996) specifies an extraction with hot water and precipitation of proteins with Carrez reagents (potassium hexacyanoferrate(II) and zinc acetate solutions), followed by acidification of the filtered extract with nitric acid before addition of excess silver nitrate. The silver chloride precipitate is coagulated with nitrobenzene and the residual silver nitrate titrated with potassium thiocyanate. In the AOAC method, the sample is treated with excess silver nitrate before extraction by boiling with dilute nitric acid and titration of residual silver nitrate is with ammonium thiocyanate. This method is appropriate for samples with a sodium chloride content  $\geq 1\%$ .

Another ISO method (ISO 1841-2: 1996), based on potentiometric titration with a silver nitrate solution using a silver electrode, is appropriate for samples with a sodium chloride content  $\geq 0.25\%$ . The sample is dispersed in water and an aliquot is acidified by addition of nitric acid, prior to titration.

Alternative methods for salt determination include use of a chloride ion-selective electrode and a semi-quantitative indicating strip method based on the reaction of chloride ion with silver chromate to produce silver chloride.

The salts associated with cured meats, nitrates and nitrites, are assayed by aqueous extraction and colorimetric determination. The ISO methods involve extraction in hot water containing borax solution and deproteinization of a portion of the extract with Carrez reagents. Nitrite (ISO 2918: 1975) is determined directly by formation of an azo dye with sulfanilamide and *N*-(1-naphthyl)ethylenediamine dihydrochloride which is measured at 538 nm. Nitrate (including nitrite) (ISO 3091: 1975) is determined by cadmium reduction to nitrite and azo dye formation. Reduction of nitrate to nitrite may be carried out on a special column (as in the ISO method) or using 'spongy' cadmium. Care must be taken to prevent interference from ascorbic acid if it is present in the sample at relatively high levels ( $> 20 \mu\text{g ml}^{-1}$ ).

Other methods for nitrates and nitrites include the AOAC procedure in which *m*-xylenol is nitrated and the nitro-xylenol is distilled into sodium hydroxide solution to form a colored sodium salt that is determined with ultraviolet spectrophotometry at 450 nm. Gas chromatography with electron capture detection and high-performance liquid chromatography have been used for determination of nitrate and nitrite derivatives.

Of particular interest in cooked cured meat products is the determination of nitrosamines,

carcinogenic products resulting from the reaction of secondary amines with the nitrites used for curing. The AOAC official method is based on distillation under vacuum of the nitrosamines from the sample in mineral oil into a trap. The trapped nitrosamines are collected in methylene chloride, concentrated by evaporation, and determined by gas chromatographic analysis using a thermal energy analyzer. Recently, a method was approved by the AOAC for the following three volatile *N*-nitrosamines in minced meat: *N*-nitrosodimethylamine, *N*-nitrosopyrrolidine, and *N*-nitrosomorpholine. In this method, the sample is mixed with anhydrous sodium sulfate and Celite, packed into a glass chromatographic column, and eluted with pentane-dichloromethane. The eluate passes through a second column containing acid Celite, on which the nitrosamines are trapped. The nitrosamines are eluted from this second column with dichloromethane, the eluate is concentrated, and the nitrosamines determined by gas chromatographic analysis using a thermal energy analyzer.

Phosphate and polyphosphates are determined as total phosphorus in the ISO method (ISO 2294: 1974). The sample is digested with nitric and sulfuric acids and the orthophosphate is precipitated as quinoline 12-molybdophosphate. The precipitate is collected on a glass filter, dried, and weighed and expressed as phosphorus pentoxide. A similar procedure described by the AOAC is ashing of the sample at  $550^\circ\text{C}$ , boiling of the ash in dilute nitric acid and filtration before precipitation of quinoline 12-molybdophosphate.

An alternative approach to these gravimetric methods is determination procedure based on the formation of colored complexes. Orthophosphate in acidic solution reacts with molybdic acid and vanadic acid to form yellow-orange vanadomolybdophosphoric acid which has maximum absorption at 330 nm. Another approach is a two-stage reaction in which yellow phosphomolybdate is produced from the addition of ammonium molybdate to the orthophosphate in acidic solution, and the phosphomolybdate is then reduced by ascorbic acid to a molybdenum blue, which is measured at 890 nm. This last method is the basis for an AOAC-approved spectrophotometric method.

In some countries, sulfur dioxide is used as a preservative in meat products. Sulfur dioxide occurs in many forms in food but quantitative tests for the material in meat products are normally for total (free plus bound) sulfur dioxide. The AOAC method applied to meat products consists of liberation of sulfur dioxide from the sample by heating with hydrochloric acid, distillation into hydrogen peroxide solution,

which then reacts with the sulfur dioxide to form sulfuric acid, and titration with sodium hydroxide using methyl red indicator. Gravimetric determination is also possible by addition of barium chloride to the titrated liquid resulting in a precipitate of barium sulfate, which can be isolated by filtration, dried, and weighed. Special apparatus for the AOAC procedures (the modified Monier-Williams method and the optimized Monier-Williams method) have been developed.

An alternative to the hydrogen peroxide/sulfuric acid titration with alkali is distillation of sulfur dioxide from the acidified sample into excess iodine solution. A proportion of the iodine, equivalent to the amount of sulfur dioxide, is reduced to iodide, and the residual iodine is titrated with sodium thiosulfate using starch as indicator. This more rapid method is suitable for meat products where other volatile sulfur compounds do not interfere, and it has been developed for use with automated distillation systems.

Another AOAC approved method for sulfites in meat is the qualitative test based on decolorization of malachite green solution when mixed with a sample containing sulfites. This may be used to screen samples prior to quantitative determination as described above.

Two other methods have been approved by AOAC for determination of sulfites in food. One is a quantitative assay based on malachite green decolorization using flow injection analysis. Sulfite is released from a sample slurry with alkali, then the test stream is acidified to produce sulfur dioxide gas which diffuses across a Teflon membrane into a flowing stream of malachite green, and the extent of decolorization is measured at 615 nm. The other method is based on ion exclusion chromatography with sulfur dioxide being released by alkali extraction, and the diluted filtrate is injected onto an anion exclusion column linked to an electrochemical detector.

The presence of added starch in meat products is determined by a titrimetric method for reducing sugars. The ISO (ISO 5554: 1978) and AOAC describe methods for starch which involve extraction with water, clarification with Carrez reagents, and acid hydrolysis of the isolated starch. Determination of the resultant reducing sugars is by reaction with Fehling's solution (containing copper sulfate), oxidation of potassium iodide with the excess copper(II), and titration of the liberated iodine with thiosulfate, according to the Luff-Schoorl method.

Starch, and individual sugars, may be determined in meat products using enzymatic kit methods. Starch is extracted from the sample and hydrolyzed by the enzyme amyloglucosidase to D-glucose. The

quantity of D-glucose is determined by a two-stage reaction involving hexokinase and dehydrogenase enzymes. The specific glucose-6-phosphate dehydrogenase utilizes the coenzyme nicotinamide adenine dinucleotide phosphate (NADP). The reaction of the enzyme with the sugar involves reduction of NADP to NADPH, which is measured spectrometrically at 340 nm:

## Metals

Analyses for metals in meat and meat products are carried out by atomic spectrometry, generally after dry-ashing and solubilization of the ash in acid. Sodium and potassium, being present at relatively high levels in meats, are determined by atomic emission spectrometry, while other metals, such as cadmium, copper, iron, lead, and zinc, are determined by atomic absorption spectrometry. An alternative method applicable to most metals is inductively coupled plasma atomic emission spectrometry.

The AOAC method for arsenic involves ashing at 600°C, dissolving the ash in dilute hydrochloric acid with the addition of metallic zinc, and the arsenic is distilled as arsine (AsH<sub>3</sub>) into an iodine solution. Ammonium molybdate is added to the solution and, through a series of reactions assisted by heating, molybdenum blue is formed which is determined spectrophotometrically at 840 nm.

The determination of calcium in meat products, especially in mechanically recovered (or separated) meat (MRM/MSM), is an important estimation of the amount of bone material included in the meat. The AOAC method describes an acid digestion of the sample and reaction of an aliquot of the filtered digest with excess ethylenediaminetetraacetic acid (EDTA) under alkaline conditions to form a chelated complex with calcium ion. The excess EDTA is then titrated with calcium carbonate using hydroxynaphthol blue as indicator.

## Kit Methods for Additives and Metals

A variety of qualitative or semiquantitative kit methods based on indicating test strips (e.g., Merckoquant<sup>®</sup>), color comparators (e.g., Aquaquant<sup>®</sup>, Microquant<sup>®</sup>), and photometric determinations (e.g., Spectroquant<sup>®</sup>) are available. These kit methods

may be used for onsite measurements or for screening assays. Typical analytes measured are nitrite/nitrate, sulfite, phosphate, and metals.

## Analyses for Adulteration

### Meat Species Identification

The determination of the animal species contributing to the meat(s) in a meat product is important for marketing purposes. It may be necessary, in some cases, to ensure the absence of meat of a particular species, such as pork. A number of methods for meat species identification are used which are based on immunological antigen–antibody reactions, on protein isolation techniques, such as electrophoresis, or on DNA analysis.

The AOAC methods are based on agar gel immunodiffusion tests for beef and for poultry meat in meat products. These tests use stabilized reagent paper disks containing beef (or poultry) antibody and beef (or poultry) antigen. The samples are applied to the agar plate by absorbing fluids on to paper disks, which are then placed on the plate. Diffusion of antigen and antibody components occurs during incubation for 18–24 h and the immunoprecipitin lines are examined for presence of beef (or poultry) in the samples (**Figure 2**). These tests are limited in that they are suitable only where the adulterant is present at  $\geq 10\%$ .

Agar gel immunodiffusion methods have been produced as commercial kits and a further development is dipstick assays for meat species identification. The immunoreagents are immobilized on a dipstick and a color change, occurring in less than 1 h, identifies the presence of a particular meat species, with a detection limit of  $\sim 1\%$  lean meat.

**Figure 2** Agar immunodiffusion technique. (a) Illustrates the reference line formed between beef reference antigen B and anti-beef antibody A and two negative samples S. (b) Illustrates a positive beef sample on the left, shown by complete fusion of its immunoprecipitin line with the reference line. The presence of the nonspecific line shows that the sample on the right is negative for beef. (Reprinted with permission from *Official Methods of Analysis* (2000) 17th edn., AOAC International, Gaithersburg, MD, Sec. 39.1.36, AOAC International.)

Enzyme-linked immunosorbent assays (ELISAs) in kit form are most widely used giving relatively rapid and inexpensive methods for multispecies identification. A typical format for such an ELISA is to coat different strips of the normal  $12 \times 8$ -well plate with antisera formed against serum albumin of the various species of interest. An extract of the meat product is added to the antibody-coated wells, incubated to ensure antibody binding of the serum albumin, and, after washing, a second antibody coupled with enzyme is introduced. The ‘sandwich’ is visualized by addition of a substrate to the enzyme. ELISAs have been developed, also, for meat species identification in cooked meat products. These ELISAs are quite specific and sensitive ( $\sim 1\%$  of each species can be detected) but are qualitative, or at best, semiquantitative.

Methods for meat species identification based on DNA analysis benefit from the heat stability of the DNA molecule and its high specificity. Originally, DNA methods consisted of immobilization of partially purified and denatured DNA, extracted from the meat product sample, on a nylon membrane, followed by hybridization of a species-specific segment of labeled (colorimetric, fluorescent, or chemiluminescent) DNA with any complementary sequences of DNA present on the membrane. More recently, a DNA amplification method – the polymerase chain reaction – has been used, but this is a relatively expensive and technically demanding technique.

### Nonmeat Proteins

Assays to detect the presence of nonmeat proteins, such as soya protein, are based on similar antigen–antibody methodologies as are used for meat species identification. An AOAC method for soya protein in raw and heat-processed meat products uses an indirect ELISA technique. The soya protein is extracted from the sample as acetone powder and renatured by dilution with buffer. The soya protein reacts with an excess of antibody and the unbound antibody is immobilized in wells that have been coated with antigen. A second antibody conjugated to enzyme labels the immobilized antibody and substrate is added to give a color reaction, the extent of which is inversely related to the amount of soya protein extracted from the sample (**Figure 3**). This procedure is very lengthy and test kits utilizing a direct ELISA give more rapid results. Qualitative microscopic methods are also used to detect the presence of soya in meat products.

Skim milk powder or milk proteins may be used in meat products. The presence of milk powder is

**Figure 3** Schematic diagram of soya protein determination by the ELISA procedure. (Reprinted with permission from Official Methods of Analysis (2000) 17th edn., AOAC International, Gaithersburg, MD, Sec. 39.1.3; © AOAC International.)

determined by a quantitative assay for the distinctive milk sugar, lactose. The AOAC method describes the determination of lactose as a reducing sugar using Benedict solution. Prior to the determination of lactose, all other reducing sugars in the sample are fermented with Baker's yeast. Lactose may be determined directly in a procedure that involves hot-water

extraction of the sugar, freeze-drying to remove the water, formation of a silyl derivative of the lactose followed by determination using gas–liquid chromatography with flame ionization detection. Alternative methods for direct determination of the milk proteins in meat products are based on enzyme immunoassays or electrophoresis.

## Assessment of Spoilage

A number of methods are used to determine spoilage of meat. These methods are directed at measuring changes in protein and fat that indicate deterioration due to spoilage. Protein breakdown is determined through measurement of TVBN. The meat sample is extracted with trichloroacetic acid, the extract made alkaline with sodium hydroxide, the volatile bases distilled into standard acid, and the TVBN determined by back-titration with standard alkali.

Deterioration of fat causes rancidity of which there are two types – hydrolytic rancidity, caused by a combination of microorganisms and moisture, and oxidative rancidity, caused by oxygen interacting with unsaturated fatty acids. Hydrolytic rancidity is measured as the quantity of free fatty acids (FFA) in the fat; the fat is extracted from the meat into chloroform, a portion of the extract is mixed with neutral alcohol, and the FFA titrated directly with alkali (using phenolphthalein as indicator). A number of methods are available to measure oxidative rancidity including peroxide value (PV), TBA value, and anisidine value (AnV). The PV is determined on a chloroform extract by measuring the oxidation of potassium iodide to iodine through titration with thiosulfate. TBA and AnV are determined as colorimetric reactions between aldehydes and 2-thiobarbituric acid and between carbonyl compounds and *p*-anisidine, respectively.

The suitability of meat is established by ensuring that the values for TVBN, FFA, PV, TBA, and AnV are below specified levels which have been established as correlating with off-flavors in the meat.

## Limitations of Current Analytical Procedures

Analysis of meat using standard methods is relatively slow and does not give results that can be used to influence the manufacturing process. Major developments in meat analysis technology have occurred in both offline and online systems that give rapid analysis capability.

Systems based on microwave energy have been developed for determination of moisture, fat, and

**Figure 4** Spectra of homogenized raw pork at two levels of fat. (From Norris KH (1984) Reflectance spectroscopy. In: Stewart KK and Whitaker JR (eds.) *Modern Methods of Food Analysis*, pp. 167–186. Westport, CT: AVI Publishing.)

protein in meat. Automated systems are available that determine moisture and fat content gravimetrically and calculate protein using a factor, giving results within 5–10 min. Microwave energy may be used, also, to give rapid Kjeldahl digestion (10 min) for direct determination of crude protein.

A very promising technology for both offline and online applications is near-infrared (NIR) spectroscopy. NIR radiation energy causes bending or stretching of bonds such as  $-C-H$ ,  $-O-H$ , and  $-N-H$  to produce absorbance spectra (Figure 4). The absorption of energy at wavelengths in the NIR region (750–2500 nm) can be used to analyze for constituents of meat and meat products. A requirement for use of NIR analysis is the development of calibrations for the analytes of interest, involving chemical analysis of many ( $\geq 100$ ) samples representative of the ranges of analytes and variations in the product. Successful applications of NIR technology in meat analysis have been done for moisture, protein, and fat. Salt has been determined by NIR in meat products based on a displacement of the water absorbance peak at 1806 nm. The particular advantage of NIR analysis is that all analytes may be determined simultaneously. Limitations in the use of NIR analysis are the time and expense required for the development of robust calibrations and the high product specificity of calibrations, which may limit the capability of the technology to give accurate results when there are changes in product composition.

A particular attraction of NIR analysis is the possibility of using it online to monitor meat constituents continuously. Fiber optic probe technology has been successfully adapted to deliver the incident energy and record the reflected energy from the sample. A

**Figure 5** Discriminant scores plot for homogenized chicken (C), turkey (T), and pork (P) meats. (From Downey G (2003) The National Food Centre (Teagasc), personal communication.)

higher energy wavelength range of 750–1100 nm is often used to achieve sufficient penetration of energy into intact meat surfaces for nondestructive analysis online. Apart from quantitative compositional analysis, NIR has been applied to qualitative analysis, to predict tenderness of beef carcasses, meat quality of pork carcasses, and to confirm the animal species of comminuted meat (Figure 5).

A variety of technologies are being applied to online analysis of carcasses and meat cuts, total body electrical conductivity (TOBEC), video image analysis (VIA), and ultrasound scanning. TOBEC measures the interference produced in an electromagnetic field by the carcass/meat cut and this is related to moisture content and, indirectly, to lean meat content. TOBEC has been used for online measurement of the lean meat content of boxed boneless beef for over a decade and is being used also for the grading of pork carcasses and hams. VIA has been used for determining the fat/lean content of boxed beef and has been applied also to grading beef, pork, lamb, and turkey carcasses. VIA is being developed to predict the eating quality of beef. Ultrasound scanning has also been applied to automate pig carcass grading. For example, the AUTOFOM<sup>TM</sup> equipment may be more accurate at predicting the lean content of carcasses than are conventional grading probes used on the slaughterline, and the equipment gives information also on the leanness of individual cuts.

## Introduction

Many of the components in milk and dairy products can be analyzed by standard methods approved by the International Dairy Federation (IDF). In December 2000, the IDF and the International Organization for Standardization (ISO) agreed to publish standards jointly and these are printed, distributed, and sold exclusively by the ISO Secretariat. Many of the methods are also published by the Association of Official Analytical Chemists (AOAC). The World Health Organization (WHO) has approved certain methods. Some of the methods have been used for many years but, particularly in microbiology, there have been recent advances that have improved our ability to determine microorganisms more specifically.

An analysis of dairy products includes the proximates: total solids, protein, fat, energy, ash, acidity, and specific gravity, and the specifics: lactose, sodium, potassium, calcium, copper, chloride, phosphate, citrate, lactose, preservatives and antibiotics, added dyes, detergent residues, organic residues, and

microorganisms. In addition, milk itself may be analyzed for freezing point and dirt. Methods can be used for different products with a little adaptation in most cases.

## Physical Analysis of Milk

### Freezing Point

Water may get into milk from milking machinery, accidentally or fraudulently. Dilution of milk changes its freezing point. The WHO method uses a thermostatically controlled water bath cooled by electrical refrigeration and a thermistor probe. There are two types of instrument: the first determines a plateau in the freezing curve and the other, used for routine screening, reads at a fixed time from the start of freezing.

In the approved method, supercooled milk is induced to freeze by mechanical vibration that causes the temperature to rise to a plateau corresponding to the freezing point. Standard solutions of sodium chloride are used for calibration. The method gives excellent agreement between different laboratories testing the same sample of milk ( $<0-005^{\circ}\text{C}$ ). The addition of 1% water in milk raises the freezing point by about  $\sim T/100$ , where  $T$  is base freezing point of authenticated samples. Dietary, daily,

## Dairy Products

**R J Marshall**, London Metropolitan University, London, UK

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

Many of the components in milk and dairy products can be analyzed by standard methods approved by the International Dairy Federation (IDF). In December 2000, the IDF and the International Organization for Standardization (ISO) agreed to publish standards jointly and these are printed, distributed, and sold exclusively by the ISO Secretariat. Many of the methods are also published by the Association of Official Analytical Chemists (AOAC). The World Health Organization (WHO) has approved certain methods. Some of the methods have been used for many years but, particularly in microbiology, there have been recent advances that have improved our ability to determine microorganisms more specifically.

An analysis of dairy products includes the proximates: total solids, protein, fat, energy, ash, acidity, and specific gravity, and the specifics: lactose, sodium, potassium, calcium, copper, chloride, phosphate, citrate, lactose, preservatives and antibiotics, added dyes, detergent residues, organic residues, and

microorganisms. In addition, milk itself may be analyzed for freezing point and dirt. Methods can be used for different products with a little adaptation in most cases.

## Physical Analysis of Milk

### Freezing Point

Water may get into milk from milking machinery, accidentally or fraudulently. Dilution of milk changes its freezing point. The WHO method uses a thermostatically controlled water bath cooled by electrical refrigeration and a thermistor probe. There are two types of instrument: the first determines a plateau in the freezing curve and the other, used for routine screening, reads at a fixed time from the start of freezing.

In the approved method, supercooled milk is induced to freeze by mechanical vibration that causes the temperature to rise to a plateau corresponding to the freezing point. Standard solutions of sodium chloride are used for calibration. The method gives excellent agreement between different laboratories testing the same sample of milk ( $<0-005^{\circ}\text{C}$ ). The addition of 1% water in milk raises the freezing point by about  $\sim T/100$ , where  $T$  is base freezing point of authenticated samples. Dietary, daily,

and seasonal variations in the composition of milk affect the freezing point but the osmotic pressure does not change very much, so the freezing point normally remains within the range  $-0.530^{\circ}\text{C}$  to  $-0.570^{\circ}\text{C}$  (mean  $-0.540^{\circ}\text{C}$ ).

### Specific Gravity

The specific gravity of milk can be used to determine the total solids (TS) content and is usually measured by either a standard hydrometer or with a pycnometer (density bottle) after gentle mixing. The effect of different temperatures can be corrected using a table. The TS of the milk can be calculated if the fat content is known by using Richmond's formula:

$$\text{TS, } T(\%) = 0.25G + 1.2F + 0.72$$

where  $G$  is the lactometer reading at  $20^{\circ}\text{C}$  and  $F$  is the percentage of fat present. Milk has to be aged for several hours and chilled.

### Chemical Analysis

Individual methods are available for the determination of the proximates (TS, fat, protein, ash, etc.) in milk and dairy products. However, many laboratories use an infrared analyzer that measures the protein, fat, and lactose content of milk simultaneously and almost instantly. The latest instruments can analyze proximates in solid and semisolid dairy products in 50 s (Figure 1).

These instruments use near-infrared transmittance to give rapid results. For fat, infrared analyzers measure the radiation absorbed by the carbonyl groups of ester bonds in the acylglycerols (at  $\sim 5.73\text{ }\mu\text{m}$ ) or by the  $-\text{CH}$  groups (at  $\sim 3.48\text{ }\mu\text{m}$ ). For protein, the absorption at  $6.46\text{ }\mu\text{m}$  by secondary amide groups is

measured and for lactose, the absorption at  $9.61\text{ }\mu\text{m}$  by the hydroxyl groups.

### Fat

The standard method for determining fat in milk is the Gerber method. A measured quantity of milk is added to a standard amount of concentrated sulfuric acid in a special test bottle (butyrimeter). Isoamyl alcohol is added to extract the fat and then the bottle is centrifuged to separate the aqueous and fat phases. The fat phase separates into the graduated neck of the bottle and the percentage of the total volume may be read off.

The Babcock method uses a tube that is much larger than the Gerber bottle. After adding concentrated sulfuric acid and centrifuging, water is added to bring the fat column into the graduated neck of the bottle.

The Rose–Gottlieb method is also used. This method gives excellent results but requires very careful attention to detail to achieve the best accuracy. The sample is treated with concentrated ammonia and then the fat is extracted using organic solvents. Finally, the extract is dried, weighed, and expressed as a percentage of the original weight of sample.

The Werner–Schmid method is useful for sour milk and other milk-based foods. This method uses ammonia (relative density 0.88) in which the sample is dispersed followed by the addition of hydrochloric acid. The casein is dissolved by heating in boiling water. The fat is then extracted with diethyl ether, dried, and weighed.

The same methods can be used for other dairy products, cheese, cream, etc. There are different butyrimeters for the different products that allow for the different ranges of fat contents.

### Total Solids

The TS content is the mass remaining after complete removal of water and volatiles. In the standard method, a weighed sample of milk is dried under controlled conditions to constant weight. The TS is expressed as a percentage by mass. The TS of cheese is measured in the same way but washed, dried sand is placed in the drying tin and used to break up the sample into small pieces. This prevents spitting during drying which would cause losses.

The TS and thus the nonfatty solids (solids-not-fat, SNF) can also be calculated after determination of the density and fat contents.

### Protein

A number of different methods are commonly used to determine the protein content.

**Figure 1** FOSS FoodScan Lab Infra-red analyser (From *In Focus* (2002), vol. 26(1), p. 13, with permission).

In the classical Kjeldahl method, the proteins are 'digested' (wet oxidized) in sulfuric acid with a catalyst (mercury and selenium tablets now succeed by the much safer potassium and copper sulfate tablets). An acid solution of ammonium sulfate is formed which is then diluted in water. The solution is made alkaline with sodium hydroxide and heated to distil off ammonia into excess standard acid sulfuric acid. The excess acid is back-titrated with standard sodium hydroxide to determine the amount of ammonia. It is more usual now to use boric acid in which to collect the ammonia and titrate with standard hydrochloric acid. The Kjeldahl procedure has been partially automated in systems such as the Kjeltec Analyzer. Total protein can be calculated as nitrogen content  $\times 6.38$ .

The total protein, casein protein, and noncasein protein are determined by measuring total nitrogen (TN) and noncasein nitrogen (NCN) after precipitation of the casein fraction at its isoelectric point by acetic acid-sodium acetate. Casein N = TN - NCN.

Dye-binding methods use the ability of dyes to bind to charged amino acid residues of the proteins. The proteins may be separated as previously described and then treated with the dye. Dyes used include amido black and orange G. On binding to the protein they form an insoluble complex that may be removed by centrifugation. The amount of residual color in the supernatant is measured by spectrophotometry and calibrated by reference to the Kjeldahl method.

### **Titrateable Acidity and pH**

The acidity of milk, expressed as percentage of lactic acid, is normally measured by titration of milk diluted to two times its own volume with carbon dioxide-free water against  $0.111 \text{ mol l}^{-1}$  sodium hydroxide using phenolphthalein indicator. One milliliter of sodium hydroxide is equivalent to 0.0010 g lactic acid.

The pH of milk is measured directly using a pH meter. Care is needed to keep the electrode free of fat which may block the porous plug and give false readings.

The titrateable acidity and pH of other dairy products, such as cheese and during cheesemaking, are measured in the same way. For cheese, it is usual to make a slurry of 10 g cheese in 10 ml distilled water and measure the acidity or pH.

### **Lactic Acid**

In the standard method for lactic acid in milk, the proteins are removed by precipitation with phosphotungstic acid and filtration. The filtrate is acidified with sulfuric acid and lactic acid extracted in a

special extractor using ether. After adding water, the ether is evaporated off and the remaining solution neutralized. After removal of the ethanol, used to wash the solution, it is treated with ferric chloride in hydrochloric acid and a blue color develops which may be quantified at  $\sim 365 \text{ nm}$  using a spectrophotometer. Gas-liquid chromatography (GLC) and enzymatic methods are also used.

### **Lactose**

Several methods are available to measure lactose content. As lactose is optically active and rotates the plane of polarized light in proportion to its concentration, polarimetry may be used to quantify it. The proteins are first removed by precipitating them with phosphotungstic acid. This method is much less used now.

Lactose can also be measured enzymatically by hydrolysis in the presence of nicotinamide adenine dinucleotide (NAD) which is reduced to NADH (see eqns [1] and [2]). The amount formed is determined spectrophotometrically at 340 nm:

The NADH is produced in stoichiometric amounts and has an absorption coefficient of  $6.3 \text{ m mol}^{-1} \text{ cm}^{-1}$  at 340 nm. Kits are available that contain all the reagents and instructions (for example, see: <http://www.r-biopharm.com/>. AOAC International (Association of Official Analytical Chemists) also has an index of rapid test kits: <http://www.aoac.org/testkits/tkdata8.htm>).

The Lane and Eynon titration, which uses Fehling's solution (equal parts of Fehling's 1 and 2; Fehling's 1: 69.3 g copper sulfate pentahydrate in water to 1 l; Fehling's 2: 100 g sodium hydroxide, 345 g sodium potassium tartrate in water to 1 l), can also be used for the quantitative determination of lactose (and other reducing sugars). The sample has to be cleared first using standard reagents for precipitating the protein. Then the clarified sample is run from a burette into boiling Fehling's solution containing methylene blue indicator. The Fehling's is standardized using standard reducing sugar solution in the burette.

### **Ash**

Ash is the residue after incineration at  $<550^\circ\text{C}$  and comes from both the organic and inorganic

constituents. Chlorides are easily volatilized if the ashing temperature is too high. Citrate is lost completely. Samples are weighed into acid-washed crucibles that are then placed in a muffle furnace. Prior to combustion, they can be heated gently over a flame taking care to avoid inflaming the sample, or by infrared lamp, to dryness.

### Individual Proteins and Free Amino Acids

The caseins are solubilized with urea and separated by electrophoresis on polyacrylamide slab gels containing urea to prevent them from aggregating. Standards of purified caseins are used for quantification. However, this method is not very satisfactory. The whey proteins ( $\beta$ -lactoglobulin and  $\alpha$ -lactalbumin) are determined in casein-free extracts by polyacrylamide slab or disk electrophoresis. Proteins in milk may also be analyzed by fast protein liquid chromatography in which they are separated on a short column of ion exchange resin (e.g., Mono Q anion exchange column, Pharmacia Fine Chemicals, Sweden), eluted, and detected by their adsorption of ultraviolet (UV) light.

Individual amino acids can be determined in solubilized extracts using high performance liquid chromatography (HPLC).

### Minerals

Metallic cations in milk and dairy products (including sodium, potassium, calcium, and heavy metal contamination) may be measured by flame photometry ( $\text{Na}^+$ ,  $\text{K}^+$ ) or atomic adsorption spectrometry (AAS) (other elements) in which the sample is atomized in the gas flame and the adsorption is measured at the characteristic wavelength of each element.

Samples are 'wet oxidized' in concentrated sulfuric acid plus concentrated nitric acid by heating to  $\sim 400^\circ\text{C}$ . The solutions are then diluted to standard volume and used for subsequent analysis.

### Calcium

Calcium in wet-oxidized samples is determined by AAS. In principle, it can be measured by flame photometry but the lower sensitivity of instruments for the calcium flame limits the usefulness of this method.

The standard method for determining total calcium involves precipitating the proteins with trichloroacetic acid and filtering to obtain the soluble calcium. This is converted to the oxalate by adding saturated ammonium oxalate and precipitated by adding acetic acid. The calcium oxalate is washed into water, acidified with sulfuric acid, and heated over a boiling water bath to dissolve it. The hot solution ( $>60^\circ\text{C}$ )

is titrated with potassium permanganate to a first permanent pink color.

### Chloride

Chloride may be determined by the Volhard method. The sample is acidified with concentrated nitric acid and silver nitrate is added, which reacts with the chloride, and then the mixture is boiled. After cooling, the pale yellow solution is diluted and the excess silver nitrate titrated with potassium thiocyanate solution using ammonium ferric sulfate as indicator. The ash may also be used for this determination.

### Phosphate and Other Salts

Phosphate and other salts may be measured by various titrimetric and colorimetric methods. Phosphate is measured titrimetrically by precipitation of quinoline phosphomolybdate that is collected and dissolved in a small known excess of alkali and then back-titrated with standard acid. A colorimetric method based on the reaction of the phosphate with ammonium molybdate followed by partial reduction to give 'molybdenum blue' has been developed for use in auto-analyzers.

### Energy

The energy content can be measured by combustion of the residue after drying in a ballistic bomb calorimeter. However, this gives the total energy in the sample, which is not the same as the energy available for digestion. This can be approximated by calculating the metabolizable energy contribution of the fat, protein, and carbohydrate.

## Contaminants

### Contamination of Milk by Soil and Other Dirt

The standard method for determining contamination of milk by soil particles and similar dirt is in two forms. The reference method involves centrifuging after standing for 72 h and so is not used routinely. The rapid method uses a filtration technique that takes  $\sim 3$  min. The amount of visible dirt on the filter is compared visually with standard photographic disks and gives values in milligrams per liter.

### Microorganisms

Microbial contamination of milk is measured by culturing the microorganisms on suitable growth media. The most effective method is to make appropriate dilutions of milk, or suspensions of dairy products in saline or Ringer's solution, which are spread over the surface of nutrient agar in sterile Petri dishes. The

agar containing nutrients (purified meat extracts, salts, and a carbohydrate source such as glucose), is melted, allowed to cool somewhat, and poured into the Petri dishes. These are allowed to cool to set the agar into a gel. After spreading the samples onto plates they are incubated at a suitable temperature (e.g., 30°C) for 2–3 days. Colonies of microorganisms are counted by placing the dish over an indirect light source and marking each one on the outside of the dish with a felt-tipped pen. This process can be automated using image analysis equipment.

Total viable microorganisms are measured by culturing them in a complete growth medium that provides nutrients for all types (e.g., milk plate count agar). Specific types of microorganisms are determined by using media that promote their growth but retard or inhibit others. For example, 'selective' media such as violet red bile agar are used to measure total coliforms (indicator bacteria originating either in the gut of animals or in the environment). Yeasts and molds are not of importance in milk but may occur in yogurt and high-moisture low-fat spreads. Bacterial growth is inhibited by adding an antibiotic, usually chloramphenicol, to the growth medium. Its not usual practice to examine milk for pathogens but *Campylobacter*, *Listeria monocytogenes* and *Salmonella* can be detected by isolation in various enrichment and selective media before being recognized and confirmed biochemically and serologically. Mold-ripened soft cheeses can be examined for *Listeria monocytogenes* and dried milk may be examined for *Salmonella*. A wide range of rapid methods is also available. The most widely used are those based on molecular or serological techniques. Rapid methods proposed for raw milk include the adenosine triphosphate (ATP)-Limulus (horse-shoe crab) lysate test.

With the need to prevent contaminated milk from being consumed or processed, rapid tests have been developed. The direct epifluorescent filter technique is an accepted ISO test, used routinely by some laboratories. A fluorescent marker dye is attached chemically to the nucleic acid of living and dead cells. Marked microorganisms that are viable fluoresce orange under UV light and are counted automatically by an image analyzer through a microscope.

Bioluminescent methods are used to detect microbiological and somatic cell contamination of milk and milk-processing equipment. They are based on the reaction of ATP with luciferin catalyzed by luciferinase producing light, which can be then be measured in a bioluminometer. The amount of light produced is proportional to the cellular activity. Kits are available from a number of suppliers (e.g., Bio-Trace, Opto-Comp, Hy-Lite, Lumac).

## Psychrotrophs

Psychrotrophs are bacteria that grow at temperatures of 7°C and below. In milk, the main psychrotrophs are pseudomonads with *P. fluorescens* being the commonest, but *Alcaligenes*, *Flavobacterium*, and some coliforms have also been found to be psychrotrophic. They are measured by using a growth medium similar to that described above but incubated at 6.5°C for 10 days. A recent modification to the method allows the number of psychrotrophs to be measured after 25 h at 21°C, but other nonpsychrotrophs may interfere reducing the accuracy of this method. The most effective method of removing this interference is to add inhibitors of gram positive bacteria to milk and preincubate.

Pseudomonads produce extracellular enzymes that breakdown proteins, glycoproteins, fats, glycolipids, and phospholipids in milk. The enzyme linked immunosorbent assay (ELISA) method can be used to measure levels of thermostable psychrotrophic proteases and lipases in milk as a determinant of its suitability for cheesemaking or ultrahigh-temperature processing.

## Microbiological Quality

Most milk for direct sale or for use in the manufacture of dairy products is pasteurized to ensure it is free from pathogens. The quality of raw milk can be measured by the reducing effects of microorganisms on sensitive dyes. Heat treatment of the milk not only destroys potential pathogens but also the milk phosphatase enzyme.

## Dye Reduction Tests

These are not now considered sufficiently reliable because of the possible presence of psychrotrophs that do not have the enzyme systems to reduce these dyes.

**Methylene blue reduction test** This test is used to estimate the keeping quality of pasteurized milk. In principle, a measured quantity of methylene blue solution is added to 10 ml of milk in a tube. This is mixed by slow inversion, then the tube is sealed and incubated in a water bath at 37°C. A satisfactory test is given when there is no decoloration in 30 min.

**Resazurin test** The resazurin test is much quicker than the methylene blue test. Milk is mixed to aerate it and 10 ml placed in a tube. Resazurin dye solution (made from a standard tablet) is added, the tube sealed, inverted twice, and incubated at 37.5°C for 10 min. If actively reducing bacteria are present, the

resazurin dye changes from blue through pink to colorless.

### Phosphatase Activity

The enzyme alkaline phosphatase is naturally present in milk. As it is sensitive to heat it is used to measure the effectiveness of pasteurization. Milk is diluted with a buffer (pH 10.6) containing disodium phenol phosphate which is hydrolyzed by the enzyme releasing phenol. The phenol is reacted with 2,6-dibromoquinonechloroimide producing a color that is measured spectrophotometrically at 610 nm. An earlier version of this test uses *p*-nitrophenyl phosphate and the amount of yellow *p*-nitrophenyl which is released is compared with standard comparator disks.

Alternative enzymes can be measured for enhanced pasteurization, for example,  $\gamma$ -glutamyl transferase.

### Antibiotics and Other Microbial Inhibitors

There are at least 40 antibiotics and sulfonamides that may occur in milk. They can be detected and identified by both microbial and chemical methods.

**Microbial methods** Any inhibitory substance in the milk will reduce the growth of test bacteria (e.g., *Bacillus stearothermophilus*, *Streptococcus thermophilus*, *Bacillus subtilis*, *Sarcina lutea*, *Lactobacillus bulgaricus*, *Bacillus megaterium*, etc.). The disk-assay plate method uses a disk of absorbent paper that is impregnated with the milk sample to be examined and placed on the surface of an agar plate preinoculated with a suitable test organism. After incubation, the growth of the bacteria is seen as turbidity in the agar. The presence of inhibitory substances such as antibiotics which diffuse into the agar is indicated by a clear zone around the edge of the disk. The inhibitor may be identified by adding an agent that blocks its action. For example, the effect of penicillin is prevented by the addition of penicillinase, while *p*-aminobenzoic acid blocks sulfonamides. With such substances in the growth medium, the antibiotic no longer prevents the test organism from growing. Commercially available methods include Intertest, Delvotest, and TTC.

On the farm, a test kit may be used. The test organism is inoculated in tablet form into liquid medium in a test tube with a sample of the milk. An indicator in the buffer changes color if the bacteria are able to grow (i.e., no antibiotic is present). The Charm analyzer can be used for several different tests (Figure 2).

**Figure 2** Charm Sciences ROSA<sup>®</sup> portable incubator/analyzer (Reproduced with permission from Charm Sciences Inc.).

**Chemical methods** Inhibitory substances are extracted from the milk and then detected chemically by thin-layer chromatography, HPLC, fluorescence liquid chromatography, gas chromatography (GC), electrophoresis, bioautoradiography, ELISA, radioimmunoassay, enzymatic methods, and other forms of immunological methods. They are usually more specific than the microbiological methods.

### Preservatives

Although preservatives are not permitted in milk, occasionally they may be present if added accidentally or illegally.

Formaldehyde may be determined qualitatively or quantitatively, although it is only the former that is usually applied to milk. Qualitative tests include Hehner's test in which 90% sulfuric acid containing a trace of ferric chloride is poured gently into the sample. If formaldehyde is present a violet color is formed where the layers meet. This test can be carried out in conjunction with the Gerber test for fat.

Qualitative determination of boric acid is carried out by making the milk just alkaline with lime water, drying, igniting the residue, acidifying with hydrochloric acid, and placing a drop of the liquid onto

turmeric paper. The paper is then dried and the presence of boric acid is indicated by a pink or red coloration, depending on the amount present.

Benzoic acid can be determined by HPLC.

### **Pesticide Residues**

There is considerable difficulty in identifying pesticide residues because they may be present in very low concentrations. To measure organochlorine (e.g., 1,2,1-trichloro-2,3-bis-(4'-chlorophenyl)ethane) and organophosphorus (e.g., Bromophos, Malathion) residues, the fat is first extracted using a suitable nonpolar solvent. The residues are then extracted from this into acetonitrile and diluted with water. The residues are extracted into petroleum ether, purified through a column of Florisil, and eluted with petroleum ether and diethyl ether. The residues in the eluate are measured by GC with mass spectrometry (GC-MS). The software controlling the MS uses a database to identify signatures from specific groups in molecules.

### **Polychlorinated Biphenyls**

Two similar methods are used to measure polychlorinated biphenyls (PCBs). In the first they are isolated by solvent extraction along with organochlorine pesticides and measured by GLC. In the second method, they are extracted by solvents and purified on alumina or on Fluorosil columns before determination by GC-MS.

### **Dioxins**

After treatment with ammonia and ethanol, the fat phase containing the dioxins is extracted into ether-pentane, then dried and concentrated. It is cleaned up by passing it through a series of columns of base silica, alumina, and activated carbon. The eluate is analyzed by high-resolution GC-MS. The method is calibrated by using standard dioxin labeled with  $^{13}\text{C}$ .

### **Radionuclides**

Radionuclides are either naturally occurring or come from nuclear accidents such as the Chernobyl reactor disaster. Strontium-89 and strontium-90 ( $^{89}\text{Sr}$ ,  $^{90}\text{Sr}$ ), cesium-137 ( $^{137}\text{Cs}$ ), and iodine-131 ( $^{131}\text{I}$ ) are probably the most important contaminants. Strontium is adsorbed into bone, cesium mainly into muscle, and iodine only into the thyroid. These radionuclides are measured by scintillation counting of their radioactivity. Samples have to be enriched, unless the contamination is extremely high, to get counts that are significantly above background. Scintillation counting consists of placing a clarified sample into a special glass bottle with a reagent (scintillant) that

absorbs the radiation and emits light in proportion. The light is detected by a sensitive photomultiplier and expressed as counts per unit time or time to standard count.

### **Quaternary Ammonium Compounds**

These residues from cleaning agents and other fluids containing surfactants (e.g., cetyl pyridinium chloride and cetyl trimethyl ammonium bromide) may have bacteriostatic effects or cause flavor taints. To determine quaternary ammonium compounds (QACs), they are first extracted into solvent (1,1,2,2-tetrachloroethane) and then detected by the formation of a pink color with dioctyl sodium sulfosuccinate (Aerosol T), which is quantified by spectrophotometry.

Some sanitizing agents used in the dairy industry contain iodine and nonionic detergent (iodophors). Free iodine can be detected by adding an equal volume of concentrated hydrochloric acid to cold milk followed by a few drops of 2-phenylbenzo(h)chromen-4-one(7,8-benzoflavone) solution and a similar quantity of hydrogen peroxide. This is shaken and the presence of iodine is indicated by a lilac or blue color.

### **Added Dyes**

Flavored milks and other dairy-based foods may have certain added colors. The natural dye annatto is used to give a yellow/golden color. It can be detected by adding sodium hydrogen carbonate to a small amount of milk in a shallow dish and into this is placed a length of filter paper. If annatto is present, the paper is stained brown and turns pink when a drop of stannous chloride solution is added.

### **Analysis of Other Dairy Products**

**Cream** There are statutory requirements for the composition of cream. The fat content has to reach certain minima in order for cream to qualify as single, double, etc. The fat content is best determined by the Rose-Gottlieb method described above but the Gerber method may also be used.

Other components of cream, such as TS, protein, lactose, sucrose, and chloride, can be determined as described above. When acidity is determined, a control of cream, water, and dilute cobalt sulfate is used. Otherwise the method involves titration with  $0.111 \text{ mol l}^{-1}$  sodium hydroxide as before.

Some creams may contain thickeners. Starch may be detected by adding iodine. Gelatin may be detected by mixing the cream with Stokes reagent (mercury dissolved in concentrated nitric acid), filtering, and then adding saturated picric acid solution. A yellow precipitate indicates the presence of gelatin.

**Condensed and evaporated milk** The TS, fat, protein, ash, and acidity of these milks can be measured by the standard methods with slight modification in some cases. Sucrose content can be determined by polarimetry before and after inversion but more readily by HPLC.

**Dried milk products** TS, fat, protein, ash, lactose, and acidity can be measured by the standard methods. Vitamins A and D can be measured by HPLC. The burnt particles formed in the drying process can be determined after filtration by comparing the appearance of the filter pads with photographic reference standards.

**Yogurt** Most of the methods described above can be used to characterize yogurt. The fruit content can be estimated from the citric and malic acid contents using HPLC.

**Butter** Butter should be analyzed for water, salt, and butterfat content. Water can be determined by the usual drying procedure and salt by Volhard titration. Alternatively, salt may be measured by diluting it in hot water and titrating with silver nitrate using potassium chromate indicator.

The genuine butterfat content may be determined by GC or by determining the Reichert, Polenske, and Kirschner values for volatile fatty acids in butter. These are obtained by titration of various distillation fractions against  $0.1 \text{ mol l}^{-1}$  sodium hydroxide.

**Cheese** The standard methods described previously are used to determine the composition of cheese with minor modifications. The Werner-Schmid method is generally preferred for the determination of fat but the Gerber method is also used. In both cases, the cheese has to be mixed very thoroughly with the reagents.

The emulsifying salts in processed cheese (sodium, potassium, calcium and ammonium phosphate, citrate, and tartrate) can be measured from the phosphate, citrate, and tartrate content, after removing the protein with phosphotungstic acid, using standard methods.

**Nitrate and nitrite** The nitrate and nitrite content of cheeses that have been treated with these salts can be determined by reduction with cadmium followed by reaction with sulfonamide and N-1,naphthylethylenediamine hydrochloride. This produces a colored compound that can be quantified spectrophotometrically.

**Ice cream** Most of the methods described for the analysis of milk can be similarly applied to ice cream. As with cheese, moisture is determined by drying samples in dishes containing predried sand into which the ice cream is mixed. Ice cream contains considerable amounts of air that is whipped in to give the appropriate texture. This gives the product a greater volume than the starting mixture and this increase, known as 'overrun', is expressed as a percentage of the original volume. This can be calculated according to the formula:

Percent overrun

$$= \frac{\text{Volume of ice cream} - \text{Volume of mix}}{\text{Volume of mix}} \times 100$$

$$= \frac{\text{SG melted ice cream} - \text{SG ice cream before melting}}{\text{SG melted ice cream}} \times 100$$

where SG is the specific gravity.

When the ice cream is melted, all the air must be removed before measuring the specific gravity.

## Vegetables and Legumes

**Rachael J Pither**, Campden and Chorleywood Food Research Association, Chipping Campden, Gloucestershire, UK

This article is reproduced from the previous edition, pp. 1553–1561, © 1995, Elsevier Ltd.

Vegetables form an important part of a balanced diet, supplying appreciable quantities of nutrients in a relatively low-energy source food. Their attractive appearance and their range of flavors and textures make them valued foodstuffs.

The preservation of vegetables in order to provide year-round availability is not a new idea. The Indians of Bolivia and Peru have been freezing and drying potatoes as a means of preservation for many hundreds of years, with the salting of vegetables and preserving in vinegar also predating the industrial era. However, it was the development of drying, freezing, and canning techniques in the nineteenth century and improvements of these in the twentieth century, as well as modern rapid transport systems, that have led to the now year-round availability of a very large range of vegetable products.

Vegetables are important sources of vitamin C (ascorbic acid),  $\beta$ -carotene, certain B vitamins, minerals, dietary fiber and protein, with different vegetable types being particularly rich in particular nutrients.

### Major Nutrient Components of Vegetables

In common with fruits the major component of fresh vegetables is water, with contents varying from approximately 80% to 95% in the edible portion. The nutrient composition of different vegetables varies considerably and can also be influenced by agronomic factors, storage and processing or preservation technique.

#### Green Vegetables

In general, green vegetables are high in water content, low in carbohydrate, fat and protein, and moderate to high in dietary fiber and a range of vitamins and minerals. They are particularly good sources of vitamin C,  $\beta$ -carotene, folic acid, iron, calcium, phosphorus, and potassium. Many green vegetables can be eaten in the raw state, particularly leafy salad vegetables, thereby avoiding any nutrient losses due to cooking or processing.

#### Root Vegetables

Root vegetables also have a high water content and relatively low carbohydrate content; one exception to this, however, is the parsnip, which contains on average 12–13% carbohydrate, comprising almost equal proportions of sugars and starch. Carrots are the most widely cultivated of root crops and are a particularly important source of  $\beta$ -carotene, with 100 g of raw carrot containing more than the US recommended daily dietary allowance for adult men. Although carrots are poor sources of vitamin C, other root vegetables contain reasonable amounts. Root vegetables also contain significant quantities of magnesium, iron, calcium, and potassium.

#### Potatoes

Due primarily to the quantities in which they are consumed, potatoes provide the main source of vitamin C in many diets, with a survey by the National Food Survey Committee (London) showing that on average over 25% of the daily requirement of ascorbic acid in the UK diet is derived from the potato. They are also good sources of thiamin, riboflavin and niacin, as well as the minerals iron, magnesium and potassium. On average ~75% of the total solids of potatoes are made up of carbohydrates, primarily starch, making the potato a good low-fat energy source. Although potato protein levels are reasonably low, they have a high biological value and are an important vegetable protein source.

#### Legumes

Food legumes are important sources of many nutrients, particularly for people following a largely vegetarian diet. They are rich in protein and carbohydrate, and provide more energy, B vitamins and dietary fiber than green or root vegetables. Many legumes also contain a small amount of oil, which is mostly unsaturated, with soybeans being a particularly good source. Soya flour and other products derived from beans are increasingly being used in manufactured foods, with soya flour especially useful in the diet of diabetic patients.

### Sampling and Preparation Techniques

Many of the issues relevant to sampling and preparation techniques for vegetables and legumes are as discussed in the article on Fruit and Fruit Products. Vegetables are naturally heterogeneous and great

consideration must be given to sampling technique. When sampling from the field there are several considerations that have to be taken into account:

- (a) Representative samples of the crop must be taken by a recognized procedure, e.g., ISO 874: 1980.
- (b) The individual units taken must be typical of those taken in a commercial harvest; undersized, diseased or immature product that would not normally be harvested must be avoided.
- (c) Samples must be taken in a way that is reasonably representative of typical harvesting procedure.
- (d) Quantity – the following values should be considered as a minimum, where possible:
  - (i) Root crops (large) – 5 kg, not less than five items.
  - (ii) Leafy or stem vegetables (large) – 5 kg, not less than five items.
  - (iii) Leafy or stem vegetables (small) – 2 kg.
  - (iv) Fruiting vegetables (large) – 5 kg, not less than five items.
  - (v) Fruiting vegetables (small) – 2 kg.
  - (vi) Legumes – 2 kg.

Suitable preparation procedures for vegetables and legumes are detailed in Table 1. For moist materials, fine slicing devices, e.g. domestic bowl-type food processors, Waring blenders etc., produce well-homogenized samples. Chilled ball mills can be used to grind frozen vegetable samples; this reduces the risk of undesirable chemical changes occurring. Grinding is the most suitable preparation method for dry legumes or other dried vegetables, with power-driven hammer mills most often used; domestic-type electric

coffee mills are also suitable. It is important to ensure that there is no excessive heat generation during any grinding or milling process. These methods are unsuitable for wet samples owing to losses of moisture and the possibility of chemical changes resulting from heat generation. The Godex Alimentarius sampling plans for prepackaged foods (CAC/RM 42-1969) are suitable for processed and quick-frozen vegetables and legume products.

Immediately after homogenization, the sample should be transferred to a storage vessel, which should be of glass or rigid plastic, have a tightly fitting lid, and be easily labeled. If the product is not to be analyzed immediately, it should be stabilized to prevent any oxidative, enzymatic, or microbial changes. For most vegetable products the most practical effective way of achieving this is by rapid freezing and storage at  $-20^{\circ}\text{C}$ .

## Analytical Methodologies

### Moisture and Total Solids

Accurate determination of water content presents many problems due to the wide variation in food matrix and the different forms in which water occurs in foods. Standard analytical techniques, therefore, are generally chosen for their reproducibility and practicability rather than for their high accuracy.

Several standard methods exist for use in quantification of moisture content in vegetables, legumes, and their products. Full descriptions of these can be found in the Association of Official Analytical Chemists' (AOAC) *Official Methods of Analysis* and other texts on food analysis.

**Table 1** Preparation procedures for vegetables, legumes and their products

<i>Vegetable type</i>	<i>Preparation technique</i>
Leafy (e.g., cabbages, lettuce) Root (e.g., carrots, parsnips, potatoes, onions, leeks)	Select a number of individual vegetables (4–6 for large items, 10–15 for smaller items). Remove any loose soil by and brushing, and remove any extraneous matter, dead leaves, stalks, etc. Roughly chop into quarters along the longitudinal axis and take a selection of these quarters. Mechanically finely chop and mix to prepare a laboratory sample.
Legumes (e.g., peas, beans)	Take a random selection of individual seeds from the sample (ideally at least 100 g) and mechanically finely chop and mix to prepare a laboratory sample.
Stalk (e.g., celery)	Remove inedible portions (leaves, etc.), remove any extraneous matter (soil, etc.). Chop into quarters, take a selection of these quarters and mechanically finely chop and mix to prepare a laboratory sample.
Packaged vegetables (e.g., cans, jars, bottles)	For whole contents: ensure that all contents are removed from the container and macerate thoroughly until a homogeneous mixture is obtained. For drained contents: ensure that all contents are removed from the container onto a sieve of suitable mesh size. Incline sieve and drain for 2 min. Macerate total solid portion until a homogeneous mixture is obtained.

**Table 2** Drying oven methods for the determination of moisture content

<i>Sample type</i>	<i>Methodology</i>
Fresh, canned, and frozen	Dry at 69–71°C in a vacuum oven $\leq 50$ mm Hg for 2 h and repeat drying and weighing until successive weighings vary by $\leq 1$ mg.
Frozen spinach	Dry at 105°C in air circulation or gravity convection oven for 4 h and repeat drying and weighing until weight loss in 1 h is $\leq 1$ mg.
Frozen french-fried potatoes	Dry at $103 \pm 2^\circ\text{C}$ in convection drying oven for 16 h and repeat drying and weighing until successive weight loss is $\leq 0.5$ mg.
Dried vegetables and legumes	Dry at $103 \pm 2^\circ\text{C}$ in convection drying oven for 5 h and repeat drying and weighing until successive weight loss is $\leq 1$ mg.

### Drying Oven Methods

These methods measure the weight of water lost due to evaporation and give accurate comparative results, although this may not be a true measure of total water content. A summary of suitable drying times and temperatures is given in **Table 2**.

**Karl Fischer method** This is primarily used for low-moisture products and is suitable for determining moisture in dried vegetables and legumes. This sensitive titration method is based on the nonstoichiometric reaction of water with iodine and sulfur dioxide in pyridine/methanol solution.

**Near-infrared spectrometric method** This method has also been shown to be particularly suited to the determination of moisture in dried vegetables. Absorption is measured at wavelengths characteristic of molecular vibration in water and compared with a calibration equation derived from reference samples of known composition.

**Rapid methods** Many more rapid techniques are used to monitor moisture content for quality control purposes. These include rapid infrared (IR) drying, microwave drying, and electrical methods. For both the IR and microwave methods, equipment is available with built-in balances, digital displays and microcomputers to calculate moisture content.

### Carbohydrates

**Sugars** Vegetables contain substantially less glucose and fructose than is present in fruits, and sugar beets are the only significant source of sucrose. Not all methods therefore are suitable for determination of sugars in vegetables and legumes because of these lower concentrations.

It is generally necessary with vegetables and legumes to clarify the hot water extract prior to sugar determination. This is achieved by the addition of heavy metals, typically lead acetate or Carrez I and II solutions ( $\text{K}_4\text{Fe}(\text{CN})_6 \cdot 3\text{H}_2\text{O}$  and

$\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$ ), which precipitate the proteins and can also decolorize the solutions. Analysis of the water extract can then be carried out either by copper reduction methodology, enzymatically, or by liquid chromatography.

**Copper(II) reduction** Methods based on the ability of certain sugars, including all monosaccharides, to reduce copper(II) salts to copper(I) are recommended for measuring sugars in vegetable products. In the USA the Munson–Walker method as detailed by the AOAC is most commonly used, whereas in Europe the modified Lane–Eynon titration method is standard.

**Enzymatic methodology** Because of the specificity and accuracy of enzymatic reactions, and the availability of easy-to-use analytical kits, enzymatic methodologies are becoming ever more widely used in the analysis of sugars in a wide range of foodstuffs including vegetables. In common with the copper reduction methods, enzymatic methods have the advantage of simple sample preparation techniques. The enzymatic reactions involved cause the reduction of NADP to NADPH, the concentration of which is determined by spectrophotometry at 340 or 366 nm. Great care is needed in their use because of the very exact quantities involved; however, the results obtained compare favorably with more traditional methods and enzymatic methods are now accepted widely as a standard analytical technique.

**Liquid chromatography (LC)** This is now a popular and useful method of analysis which has the advantage that different sugars can be determined simultaneously. The separation technique can be carried out using strongly acidic cation exchange chromatography, or a modified silica gel amino column, with refractive index detection. This method does have certain disadvantages in that initial equipment costs are high and, owing to the sensitivity of the detectors, they are best when used exclusively and continuously for the same analysis. The latest development in LC analysis of carbohydrates uses improved anion exchange

techniques combined with pulsed amperometric detection, which is both more sensitive and selective than traditional LC methodology.

**Gas-liquid chromatography** This technique has the advantage of allowing food sugars to be determined with very high sensitivity and is the basis of an AOAC recommended method. The sample sugars have to be converted to volatile and heat-stable derivatives before analysis and this technique is not widely used in routine analysis because of the accuracy and relative simplicity of alternative methods.

**Starch** Starch is the main dry matter constituent of potatoes and legumes and is also found in many other vegetables, being important as an energy source and for its texture properties. Many methods are available for its quantification.

*Dispersion method* This method is suitable for potatoes and certain other vegetables but is not suitable for foods containing modified or presolubilized starches. It relies on the dispersion of the starch in an appropriate solution followed by determination by polarimetry. The most commonly used dispersants are hydrochloric acid and acidified calcium chloride. The solutions are then clarified and the optical rotation of the solutions measured. The specific rotation for potato starch is  $+185.7^{\circ}\text{C}$ .

*Hydrolysis methods* These involve the hydrolysis of starch to glucose which can be achieved using acid, enzymes, or a combination of these. Both acid and enzymatic hydrolysis methods can give low recoveries for modified starches; however, dispersion with dilute alkali prior to enzymatic hydrolysis can give better results. Enzymatic hydrolysis has the advantage of being specific to the starch components, whereas acid hydrolysis can lead to the breakdown of nonstarch polysaccharides.

The glucose can be determined enzymatically with a colorimetric end point or titrimetrically; commercial kits based on enzymatic hydrolysis of starch and measurement of glucose are currently available.

Although there are many variations on these two basic techniques, the accurate measurement of starch, especially in processed products where the starches may be modified or pregelatinized, remains an analytical problem.

**Structural polysaccharides** The quantification of the two main groups of complex structural polysaccharides, cellulose and pectins, involves many difficulties, partly because of the wide range of polymer size and composition that occurs.

*Cellulose and hemicellulose* These are among the most abundant carbohydrates found in vegetables and legumes. Methods for quantification generally involve the extraction of soluble carbohydrate from the defatted foodstuff, the extraction of lignin, and the hydrolysis of the remaining cellulose and hemicelluloses, followed by measurement of the resulting reducing sugars. The Englyst method for dietary fiber (see below) allows for the quantification of total nonstarch polysaccharides (NSP), soluble NSP, insoluble NSP, resistant starch, and cellulose.

*Pectin* Most standard procedures for pectin analysis in vegetables and legumes involve extraction of the pectin as pectic acid followed by precipitation. Aqueous extraction of the pectin is followed by saponification with cold alkali, acidification, and the quantification of the precipitate. The pectic acid can be precipitated as calcium pectate or, as in the AOAC procedure, using ethanol.

*Crude fiber* Crude fiber analysis is a measure of food components that are indigestible and is determined as material insoluble in dilute acid and dilute alkali under standard conditions. The basic method involves the defatted sample being boiled, first in 1.25%  $\text{H}_2\text{SO}_4$  and then in 1.25%  $\text{NaOH}$ , with the residue being filtered, dried, weighed, incinerated, and reweighed. The loss in weight on incineration is taken as the crude fiber content.

Many methods exist, mainly modifications of this basic technique, with the AOAC detailing a widely used version. Automated systems also exist, e.g. the Fibretec system in which the sample remains in the same glass crucible throughout the analysis. Crude fiber analysis is commonly carried out in cereals, animal feeds, including legumes, and flours; however, it is also used as an indicator of succulence in fresh vegetables.

**Dietary fiber** The determination of dietary fiber has increased greatly in importance in recent years; however, due partly to lack of a clear definition for dietary fiber, several standard methods exist.

*AOAC enzymatic gravimetric method* The samples are dried, with fat extracted if necessary, gelatinized with heat-stable  $\alpha$ -amylase and enzymatically digested with protease and amyloglucosidase to remove protein and starch. The soluble dietary fiber is then precipitated using ethanol, the residue filtered and washed, and corrections made for indigestible protein and ash. This method is widely used in the EC and the USA.

*Englyst method* Samples are defatted if required and any starch present is gelatinized and then removed by enzymatic digestion. The remaining polysaccharides are hydrolyzed by sulfuric acid and the resulting sugars can be measured either colorimetrically or by using gas chromatography. This method can be used to determine both total NSPs and resistant starch and is a recognized method in the UK and Canada.

### **Vitamin C (Ascorbic Acid)**

There are two standard procedures for vitamin C determination in vegetables and legumes. The sample preparation is common to both and involves maceration/dilution of the sample in a stabilizing solution, such as 5% metaphosphoric acid or trichloroacetic acid, followed by filtration. The ascorbic acid can then be determined by titration with 2,6-dichloroindophenol, where the ascorbic acid reduces the oxidation/reduction indicator dye to a colorless solution; or by fluorimetric detection, in which the ascorbic acid is oxidized to dehydroascorbic acid, which then reacts with *o*-phenylenediamine (1,2-diamino benzene) to produce a fluorophore. The latter method has the advantages that it is suitable for colored solutions and can be used to measure levels of naturally occurring dehydroascorbic acid as well as ascorbic acid. Many other methods are available for determination of vitamin C with the use of LC techniques, currently the subject of much interest. Reversed-phase LC techniques can be used to determine dehydroascorbic acid, ascorbic acid, and their isomers.

### **Carotenoids**

$\beta$ -Carotene, the most important carotenoid precursor of vitamin A, is found in carrots and many dark-green or yellow vegetables. In the average diet,  $\beta$ -carotene provides approximately one-third of the vitamin A intake.

For accurate determination of carotenoids, LC is the preferred technique and many, LC procedures have been published. Generally the sample is extracted into a solvent before being analyzed by reversed-phase LC with UV absorbance detection. These methods have the advantage of being able to detect and quantify individual carotenoids, allowing for more accurate calculation of vitamin A activity.

UV-visible spectrophotometric methods can also be used, such as are detailed in the AOAC *Official Methods of Analysis*. They are less accurate and less selective than LC methods as they measure total carotenoids; however, they offer a rapid, relatively simple analytical procedure.

### **B Vitamins**

Vegetables and legumes are good sources of many B vitamins, including thiamine and niacin (potatoes, legumes), pyridoxine (potatoes, green vegetables, peas), folic acid (green leafy vegetables), and pantothenic acid (legumes). The analysis of B vitamins is a very complex and detailed subject. Many analytical methods are available, although much work is still required in order to provide standard, reliable, reproducible measurement in all food types.

Several B vitamins, including folic acid, niacin, pyridoxine, and pantothenic acid, are routinely determined using microbiological assays, details of which can be found in the AOAC *Official Methods of Analysis*. Standard methods for thiamine determination using fluorimetric detection are also detailed in the AOAC methods; in addition, LC techniques are now being used routinely for thiamine and other B vitamins, e.g., riboflavin.

### **Protein**

The protein content of vegetables and legumes is most commonly estimated from the organic nitrogen content, determined using the Kjeldahl procedure. This can lead to slight inaccuracies due to the presence of nonprotein nitrogen compounds; however, the content of these is usually very small when compared to protein content. The Kjeldahl method is based on the wet combustion of the sample, by heating in sulfuric acid in the presence of a metallic catalyst, in order to reduce the organic nitrogen to ammonia, which is retained in solution as ammonium sulfate. The digest is made alkaline by the addition of sodium hydroxide and steam distilled to release the ammonia, which is then trapped and titrated. Many modifications of the basic method have since been carried out. The AOAC details both macro-Kjeldahl and micro-Kjeldahl methods. The former uses mercury as a catalyst during digestion; the ammonia is trapped, after distillation, in a standard acid solution which is then titrated against sodium hydroxide. The latter uses boric acid to trap the released ammonia which is then titrated against dilute acid. Many automated systems have been developed based on the Kjeldahl method. These instrumental systems include digestion in an electrically heated aluminum block digester, followed by rapid steam distillation of ammonia into acid and titration, either manually or automatically, with colorimetric or potentiometric detection.

Rapid automated systems, employing high-temperature combustion for removal of the nitrogen from the sample and a thermal conductivity detection system for measurement of the released

nitrogen, are also now available, allowing protein measurements to be carried out in <10 min.

Analysis of the individual amino acids is not normally a part of routine nutritional analysis; however, as proteins from plant sources, legumes, etc. can be deficient in certain amino acids, it is sometimes required. For this the proteins are extracted and assayed by thin-layer chromatography, gas chromatography, or LC.

## Fat

Most vegetables and legumes contain little naturally occurring lipid, the exceptions to this being soy bean, groundnut, and winged bean. Lipid is present in both free and bound forms and the amount extracted will depend on the method of analysis used. Free lipid consists essentially of neutral fats (triglycerides) and free fatty acids, which can be determined by extraction of the dried material with petroleum ether or diethyl ether. This method is suitable only for frozen fried vegetable products, e.g. french-fried potatoes, where a 'free' or 'crude' fat content is sufficient. Bound lipid can be released by acid hydrolysis, the extract filtered, and the lipid extracted as for free lipid. The latter method is suitable for a very wide range of foodstuffs including vegetables and legumes. Automated systems are widely available based on these methods, most comprising an acid hydrolysis unit and a Soxhlet extraction unit. The finely ground sample is boiled in hydrochloric acid, filtered, dried, and extracted using light petroleum ether or diethyl ether.

The Bligh and Dyer technique is based on the homogenization of wet foods with chloroform and methanol. Further addition of chloroform and water leads to the separation of the phases, with the lipid contained in the chloroform layer. The AOAC details a similar extraction method based on chloroform-methanol extraction, the advantage of these methods being that no heating stage is involved and the lipid extract can then be analyzed to determine the individual fatty acids.

Many rapid methods are now available for estimation of fat content. The Foss-Let fat analysis system determines the fat content as a function of relative density of a perchloroethylene extract of the sample. It was designed for analysis of oilseeds, but is also applicable to other foods. The method is very rapid and its accuracy is comparable to other standard methods. Nuclear magnetic resonance (NMR) spectrometry is a rapid, nondestructive method also suitable for determining the fat content of oilseeds. The NMR value is related to the total hydrogen content of the lipid, with actual lipid content calculated from calibration tables.

## Fatty Acids

Legumes contain predominantly unsaturated fatty acids; there are exceptions to this, with certain legumes containing appreciable proportions of saturated fats. In order to determine accurately the fatty acid profile of legumes, the fat portion must be extracted without heating; chloroform-methanol extraction methods are therefore widely used, e.g., those of Bligh and Dyer, Karow.

Analysis of the fatty acid profile of the extracted fat is now almost exclusively carried out using gas-liquid chromatography (GLC). Standard methodology for this technique is detailed by the International Union of Pure and Applied Chemistry (IUPAC). It involves the saponification of the extracted fat to break down glycerides, with the liberated fatty acids being esterified in the presence of methanol and boron trifluoride. Fatty acid methyl esters are then extracted with heptane and analyzed using GLC with flame ionization detection.

This allows for the percentage composition of individual fatty acids present in the sample to be determined, enabling levels of saturated, polyunsaturated, and mono-unsaturated fats to be calculated.

## Salt

Sodium chloride levels are routinely determined in canned vegetables and legumes. Titrimetric methods are most commonly used with the sodium chloride first isolated by either ashing at 500–550°C, followed by aqueous dissolution of the ash and titration with silver nitrate solution (Mohr method), or by boiling the food in dilute nitric acid, adding excess silver nitrate and back-titration with potassium thiocyanate (Volhard method). Of these, the latter method is generally more accurate than the former method; however, it is also more time-consuming.

As well as these titrimetric methods, the AOAC details a potentiometric method that is also recommended in Codex Alimentarius standards. The vegetables or legumes are dispersed in water and acidified, with the soluble chlorides titrated potentiometrically with silver nitrate. Many instruments are also now available with ion-selective electrodes that can be applied to the determination of salt in foods. They offer reasonable accuracy with ease of use and are particularly suitable for quality assurance purposes.

## Minerals (Metal Compounds)

The AOAC and Codex Alimentarius methods for determination of potassium and sodium by flame atomic emission spectrometry are suitable for the analysis of many wet vegetables. These methods have the advantage of quick and simple sample

preparation, aqueous dilution of sample, filtration and rapid, reasonably accurate detection. The samples can be aspirated directly into the flame and the readings quantified by comparison with a range of known standards. Atomic absorption spectrometry (AAS), however, has many advantages; increased accuracy and low-level sensitivity and a far wider range of detectable elements. The dry-ashing sample preparation technique required, though simple, can take a relatively long time; however, it is suitable for all types of samples.

Many elements are essential in the diet at trace levels, although at higher concentrations some possess toxic properties, examples being zinc, copper, and selenium. Vegetables and legumes are routinely tested for trace element content, e.g., canned products for tin, iron, copper, and zinc; vegetable juices for copper, zinc, and lead; potatoes for copper, zinc, and iron. Statutory limits exist for many trace elements in foods, e.g., lead and arsenic. AAS is widely used for trace metal analysis as multi-element determinations can be made on a single sample; however, other methodologies are applicable, including inductively coupled plasma-atomic emission spectrometry and colorimetric methods such as the determination of copper as its diethyldithiocarbamate.

### **Phosphate**

Certain vegetables, especially potatoes and cabbage, are good sources of phosphorus. In order to determine the phosphorus content, the sample is ashed and dissolved in hydrochloric acid; the phosphate can then be determined titrimetrically or colorimetrically. The most widely accepted method is a colorimetric (visible spectrophotometric) method based on Mission's reagent, which relies upon the reaction between the acidified sample solution and an acidic reagent containing molybdic acid and vanadic acid, to produce the stable orange-yellow molybdovanadophosphoric acid.

### **Quality Assurance**

A range of analyses and tests are carried out on vegetables, legumes, and their products as a means of quality control, and many regulations and specifications exist in relation to this. These include the Joint FAO/WHO Food Standards Programme (Codex Alimentarius), the US Department of Agriculture (USDA) standards for grades of processed products, the British Fruit and Vegetable Canners Association Codes of Practice, and EC directives.

The range of analyses carried out to determine compliance with quality and specification

requirements can include pH, titratable and volatile acidity; total solids, water-insoluble solids, alcohol-insoluble solids; sugars; ash, sodium chloride, trace metals, heavy metals; preservatives, e.g., sulfur dioxide, sorbic acid, benzoic acid, and benzoates; nitrates and enzymatic activity, e.g., peroxidase.

In general, the specification or quality document specifies methods to be used; however, the following are standard recommended methods as detailed in AOAC and Codex standards.

#### **Alcohol-Insoluble Solids**

This is usually measured in both canned and frozen peas and is an indication of maturity. The well-homogenized peas are boiled in ethanol, and filtered using a Buchner funnel. The residue is washed repeatedly with 80% ethanol to remove all soluble substances. The alcohol-insoluble solids are dried, weighed, and their percentage content calculated.

#### **Organic Acids, Acidity**

Measurement of titratable acidity is routinely carried out in many canned or pickled vegetable products, with the acidity calculated as the predominant acid. The sample is diluted in distilled water and titrated against dilute sodium hydroxide to either the phenolphthalein end point or to pH 8.1. Volatile acidity, generally expressed as acetic acid, can be measured by distilling the sample in a steam distillation apparatus, with titration of the distillate as above. Individual acids can be determined using a range of techniques including chromatographic and titrimetric methods fully described in the AOAC document, and enzymatic methodologies with commercial enzyme-based test kits now available for many acids. LC techniques are also available, facilitating identification and quantification of a range of organic acids.

#### **Preservatives**

The use of preservatives in fresh and processed vegetables and legumes is tightly controlled worldwide, e.g., in the UK under the Preservatives in Food Regulations (1989), while in the EC a directive is currently being prepared on Food Additives (excluding colors and sweeteners).

Sulfur dioxide (SO<sub>2</sub>) is generally measured by indirect methods. The AOAC describes a modified Monier Williams method, while the Codex Alimentarius standards and EC directive recommend the modified Tanner method; both are based on similar principles, involving the distillation of the SO<sub>2</sub> from an acidified aqueous suspension of the food. The evolved gas is subsequently trapped in

hydrogen peroxide where it reacts to form sulfuric acid, which is then titrated against dilute sodium hydroxide.

Benzoic acid and sorbic acid can both be extracted using modified Monier Williams distillation methods and quantified spectrophotometrically, or in the case of benzoic acid, by thin-layer chromatography. LC and GLC methodologies are available and routinely used, having the advantage of simultaneous quantification of both benzoic acid/benzoates and sorbic acid.

### Chemical Residues

Fresh vegetables and legumes in particular may also be analyzed for the presence of chemical residues. These may be present due to specific horticultural and agricultural practices (pesticides, herbicides, etc.), environmental contamination, or through the use of certain permitted additives. Detection and quantification of these residues is a complex analytical problem. Most methods used are based on solvent separation coupled with chromatographic determination using either LC, GLC or GC-mass spectrometry (GC-MS).

*Pesticide residue screening* A procedure for determining levels of organophosphorus and organochlorine pesticide residues suitable for vegetables and legumes can be found in the USA Food and Drug Administration Pesticide Analytical Manual and in AOAC methods. These methods involve the extraction of the sample into acetonitrile, with the residues being partitioned into petroleum ether. Depending on the nature of the extract, residues can then be analyzed directly, or cleaned up using Florisil or alumina columns. Analysis is by GC with nitrogen-phosphorus or flame photometric detection for organophosphorus residues, and electron capture detection for organochlorine residues.

*Nitrate and nitrite* Considerable attention is currently being paid to the levels of nitrate being found in vegetables with surveyed data ranging from 1 to 10 000 mg kg<sup>-1</sup>. Ion chromatography (IC) is a widely used method for measuring nitrate and nitrite in vegetables and their products; however, for rapid routine screening procedures electrometric measurement systems are available. A standard LC technique involves the extraction of the sample with hot water, filtration, and a sample clean-up procedure using a solid-phase extraction cartridge. The sample is then analyzed for nitrate and nitrite by IC to separate the ions, with detection by UV absorption at 214 nm.

### Enzymatic Activity

The quality of vegetables and legumes, their color, appearance, flavor, aroma and texture, can be greatly affected by endogenous enzyme activity. The effectiveness of heat-processing, e.g., blanching of vegetables for freezing, in terms of enzyme inactivation, is generally assessed by testing for peroxidase activity, peroxidase being one of the more heat-stable enzymes.

The AOAC details a titrimetric procedure for the quantification of peroxidase activity; however, for routine quality assurance a rapid spot test method is generally used. This is based on the color reaction catalyzed by peroxidase which involves guaiacol in the presence of hydrogen peroxide. The development of a brown/red color on the vegetable, after addition of the substrate, indicates that the concentration of active enzymes may be sufficient to cause a noticeable deterioration in quality.

An additional method for the assessment of adequacy of blanching is based on the detection of residual lipoxygenase. The lipoxygenase catalyzes a reaction between linoleic acid and oxygen to form a hydroperoxide. This product reacts with potassium iodide to form iodine, giving a brown coloration which can be measured spectrometrically.

### Rapid Methods

Research into new analytical techniques for foodstuffs continues, striving for greater accuracy, sensitivity or simplicity, for more rapid methods, for simultaneous multielement analysis, etc. Chromatographic techniques, e.g., LC, GLC, GC-MS, have led to great improvements in the levels of accuracy, sensitivity, and detection that can be achieved for many analytes including carbohydrates, certain vitamins, chemical residues, and additives. Work is still required, for instance, in the area of vitamin analysis in order to provide standard techniques that are applicable to all food types and that would enable concurrent multi-vitamin analysis to take place. Many of the microbiological assays currently used for vitamin determination involve long incubation times and more rapid techniques are needed.

This need for rapid analytical systems extends across most of the routine nutritional and quality assurance analyses. Recent advances in near-IR technology have led to instrumentation capable of rapid quantification of moisture, fat, and protein levels in certain foods; however, this area is still quite limited.

## Major Analytes

Lipids that are solid at ambient temperatures are referred to as 'fats' while those that are liquid are called 'oils'. Two main groups, having significantly different natural functions and structures, can be classified as the 'neutral lipids' (acylglycerides, fatty acids, alcohols, hydrocarbons, waxes) and 'polar' lipids (glycolipids, phospholipids). Neutral lipids generally form part of an energy store, while polar lipids are functional molecules in the structure of membranes.

Fatty acids (FAs) form homologous series of 'straight' chain carboxylic acids, with generally even numbers of carbon atoms. These vary typically from C4 to C30, with the majority lying between C10 and C22. Regio-specific desaturase enzymes yield an important series of FAs that contains one or more double bonds, of the *cis* isomeric form. For multiple double bonds, each pair is normally separated by a single methylene unit ( $-\text{CH}_2-$ ). The series of unsaturated FAs synthesized in plants is different from that in animals. It is important analytically to recognize this fact, particularly where nutritional profiling might be being done, as the difference creates the requirement by animals for the 'essential dietary fatty acids' produced by plants. By combining desaturation and chain elongation, animals create two main

series of polyunsaturated fatty acids, the  $n-6$  and  $n-3$  (measuring from the methyl end) with chain lengths usually up to C22.

Exceptions to the generality of straight chains are FAs substituted with hydroxy, keto (oxo), and epoxy (oxirane) groups and FAs with unusual unsaturation. Methyl branched FAs occur mainly in bacteria, but also naturally in the fat of ruminant animals together with a series of odd-chain fatty acids.

Triacylglycerides (TAGs) are fatty acid triesters of glycerol. The hydrolysis products of TAGs are FAs together with diacyl- and monoacyl-glycerides. Due to acyl transfer diacylglycerides exist in the 1:2(2:3) and 1:3 forms. Monoacylglycerides can exist in the 1( $\alpha$ ) and the 2( $\beta$ ) forms, but are predominantly in the  $\alpha$  form. Despite the potential structural complexity, most of the TAGs that the food analyst encounters are composed of a normal range of FAs. There is considerable conformity of structure in natural TAGs. This is a bonus for the analyst making differentiation between species of, for instance, seed oils easier, even after allowing for varietal (cultivar) differences. **Table 1** shows typical data for some edible fats.

Polar lipids are conveniently divided into phospholipids and glycolipids. This is not entirely adequate, but it will serve here to describe the structural types found in food. Phospholipids fall into two main groups. The phosphoglycerides carry an *sn*-3 phosphate with a nitrogenous base such as choline or ethanolamine (other groups linked to this phosphate may be inositol or glycerol). In the sphingosyl phosphatides sphingosine is esterified with, for

Note: Carbon number relates to the sum of the carbon atoms in the three fatty acid chains of a triglyceride. Thus, C<sub>54</sub> might be made up of 18 + 18 + 18, 16 + 18 + 20, etc. No distinction is made, in this analysis, between saturated and unsaturated fatty acids of the same chain length. Data can vary between batches of fat or oil. Large differences can be found between different cultivars and varieties of the same plant.

instance, phosphorylcholine. Glycolipids feature widely in nature. The structure is a 1:2 diacylglyceride with the *sn*-3 hydroxyl glycosidically linked to a mono-, di-, or trisaccharide. The mono- and di-galactosyldiglycerides are very abundant, particularly in cereal lipids.

Other common food lipids are the sterols and tocopherols. Sterols are generally present in natural oils as both the free sterol and sterol fatty esters. Animal fats exhibit solely cholesterol while plant lipids contain a range of phytosterols. Tocopherols are found in vegetable oils as a mixture of four isomers:  $\alpha$ -tocopherol (true vitamin E) and  $\beta$ -,  $\gamma$ -, and  $\delta$ -tocopherol. Four unsaturated analogs, tocotrienols, exist with the same numbering terminology and are particularly abundant in palm oil.

## Sampling, Preparation, Extraction of Lipids

Obtaining the lipid in suitable form for analysis may be the most difficult stage of sample analysis. This step can be responsible for the degradation of lipids and the formation of artifacts. There are a number of important considerations to be made if the analytical results are to give a true representation of fat composition:

- the sampling procedure,
- the extraction procedure,
- processing temperatures,
- the possible exclusion of air,
- the lighting conditions,
- the surface area of lipid films during concentration,

- the possible addition of antioxidants, and
- the storage temperature.

Representative sampling of a bulk of material is not easy. Only gram quantities are required for analysis, but this size of sample may have to represent many tons. The analyst may have to make assumptions about the contents and a conclusion about homogeneity. Bulk fat storage tanks ideally will be heated to maintain a temperature of 5–15°C above the clear point of the fat (the point at which no crystalline fat exists). The contents are unlikely to have been mixed, other than by agitation during transport and pumping from one tank to another. Bulk oils can exhibit layering due to density gradients and if storage temperature drops to, or slightly below, the clear point, the oil will begin to crystallize causing sedimentation.

Sampling at several different levels and in different quadrants of a tank is normal. The International Organization for Standardization developed the International Standard–ISO-5555. Animal and Vegetable Fats and Oils Sampling. The British Standard BS 627 (1982) forms the basis of the International Standard. The Standard includes: sampling technique; methods and apparatus for sampling; packaging and labeling of samples; dispatch of samples; preparation of a sampling report. Any sampling from a large bulk of fat must follow the procedures laid out in the Standard as the sample and the report are considered to be legal evidence in disputes.

Smaller quantities of fat (0.5–25 kg) should be melted and mixed very well before sampling. For measurement of the oxidation level, a core sample should be taken, before melting, with a trier tube

(refer to BS 809) or other hollow tube. This sample is gently melted under nitrogen and mixed before determination of, e.g., peroxide value (PV).

Emulsified and plasticized fat spreads are already homogeneous, easily sampled, and have published standard methods for their processing (IUPAC 1979). For other food products, it is important that a homogeneous sample of the food is obtained by careful blending.

The ester bonds and unsaturation in lipids are vulnerable to hydrolysis or oxidation, so that any manipulations or procedures (and subsequent storage) must take account of these facts. Lipid hydrolysis is mainly an issue of residual active lipase enzymes or microbial contamination. If fresh samples become bruised or are frozen, tissue damage releases hydrolytic enzymes. Lipid oxidation is a worse problem, particularly with highly unsaturated marine oils. Susceptibility to oxidation is enhanced in the presence of even trace ( $\text{mg kg}^{-1}$ ) amounts of copper, nickel, and iron. Lipid oxidation is a free-radical process catalyzed by light of wavelengths below 400 nm. Therefore, care should be taken during process and storage of highly unsaturated samples.

The extraction of the lipids is an important procedure in analysis. The procedure used will depend upon the structure of the matrix containing the lipid and the composition and physical state of the lipids. For instance, the matrix may contain emulsified water as in a low-calorie fat spread. This can generally be separated into fat and aqueous layers by warming at 45°C. Fresh meat contains a significant amount of water and will require homogenization in mixtures of methanol and chloroform, followed by partition of the extract against salt solution. The lipids are found in the lower chloroform phase. However, the partial solubility of some of the more polar lipids needs to be considered as does partition at the water/organic interface. These can result in quantitative losses if care is not exercised when collecting the organic extracts.

Fresh green vegetables should first be homogenized in 2-propanol to deactivate lipases, which otherwise might be activated by some organic solvents. The solids are further extracted with chloroform/2-propanol. The lipids in both extracts are combined.

The fat in coffee whiteners is encapsulated within a water-soluble carbohydrate matrix, making it unavailable to extracting solvents. Dry powder extraction will typically achieve only 1–5% of the fat. To obtain the total fat:

1. Disperse powder in warm (40°C) water and follow by solvent extraction. This will extract 95–100% of the fat in a gentle way. Or

2. Strong acid hydrolysis (Weibull–Berntrop procedure) followed by solvent partition. This is aggressive and can lead to fat oxidation.

The lipids in cereal flours (e.g., wheat) are highly structural and difficult to extract quantitatively:

1. Total lipid is estimated by gas chromatography after acid hydrolysis of the flour in the presence of a known amount of heptadecanoic acid internal standard.
2. Nonstarch lipid is extracted from flour with cold, water-saturated, *n*-butanol under standard conditions.
3. The residue from extraction (2) can be used to obtain the starch lipid by resuspending the solids in methanol, centrifuging, and recovering the solids.
4. The final solids are extracted with water-saturated *n*-butanol at 95–100°C for 60 min, repeating this five times to yield the starch lipids.

Marine organisms present particular problems due to high levels of lipid unsaturation together with high water and protein contents. The following procedure can provide a protected environment under a carbon dioxide blanket: The tissue is cut into small pieces at water/ice temperatures and homogenized in a kitchen food processor, together with enough pelleted solid carbon dioxide to fully freeze the material to  $\sim -40^\circ\text{C}$ . The powdered sample is extracted with chloroform–methanol mixtures that have been pre-cooled with cardice to  $-50^\circ\text{C}$ . This whole mixture is left to reach ambient temperature with occasional mixing and then processed using precautions against lipid oxidation.

## Standard Methods and Quality Assurance

Analytical precision and accuracy require standardization of methodology. Techniques require proving with standards and reference materials and should be tested regularly by blind inclusion of these materials into normal analytical practice. In this way the statistical variability of results can be built up providing improved confidence. The analyst can draw upon standard methodology from international authorities such as the International Union of Pure and Applied Chemistry (IUPAC), British Standards Institution, American Oil Chemists' Society (AOCS), International Organization for Standardization (ISO), Deutsche Gesellschaft für Fettwissenschaft, and Association of Official Analytical Chemists (AOAC). The priority is to standardize the chosen

methodology in the laboratory and ensure consistent practice.

Quality assurance methods commonly used are for the determination of free fatty acid (FFA), PV, iodine value (IV), anisidine value (AnV), Rancimat induction time, and *trans* value (TV).

Crude oils may be up to 15% FFA, while refined oils will be <0.1%. Measurement of FFA is normally done by titration of an ether-ethanol solution of the fat with standardized aqueous sodium or potassium hydroxide, in the presence of phenolphthalein indicator (see ISO 660: 1983). This method is very accurate, using the molecular weight of oleic acid (282) for all calculations. Accuracy is improved by using the average molecular mass of the fatty acids in the fat, calculated from the FA composition (e.g., for palm oil 256 is used, for palm kernel/coconut oil 200 is used). The results are expressed either as acid value; the number of milligrams of potassium hydroxide required to neutralize 1 g of the fat, or, FFA%; the percentage concentration of oleic acid equivalent to the free acids present.

PV is normally assessed using the Wheeler procedure: AOCS (1984) method CD 8-53 (73); and IUPAC method 2.501. The determination should ideally be carried out under tungsten lighting as ultraviolet light liberates iodine from potassium iodide in solution, in the presence of oxygen, creating high blanks. The liberated iodine is titrated with standard sodium thiosulfate. Results are expressed in Standard International (SI) Units. Some laboratories express the result in different units, which may be related to the SI units by the factors shown in the Table 2.

The interpretation of results requires some knowledge of the sample and sample processing history. For instance, low values do not necessarily indicate 'good' quality fats; organic lipid peroxides are not stable at temperatures above 50°C so that in deep fat fryers operating at up to 180°C, one would not expect to find much peroxide. The half-life of peroxides can be extremely short under frying conditions and the sample requires a standard amount of time after removal from the fryer (typically 30 min) before analysis providing more meaningful results.

IV measures the level of unsaturated components in a fat equivalent to a weight of iodine reacting with 100 g of the sample. The sample is reacted under standard conditions with a known amount of iodine (iodine trichloride as Wijs solution) in the dark (BS684 section 2.13, 1981; and ISO 3961, 1979). Unreacted iodine is liberated chemically and back-titrated with sodium thiosulfate to yield an IV. A minimum IV can be calculated from the FA composition determined by gas chromatography. The titrated IV may be higher due to the presence of other iodine-positive components. The technique assays unreacted reagent therefore, it becomes essential that the amount of Wijs reagent used is very accurately measured. A purpose-designed, exact-volume dispenser is better than using a burette. Precision of technique is very important to the reproducibility of IV measurement. A common reason for error is incorrect ratio of fat and reagent. For the reaction to be complete and the back-titration to yield a satisfactory value, there must be a minimum excess level of Wijs reagent of ~50%. The weight of sample fat used for the estimation depends upon the expected IV and may be calculated from the equation below. For a totally unknown sample this amount may be difficult to judge requiring a test IV to be carried out:

$$\text{Weight of sample (gm)} = \frac{12.69 \times M \times V_R}{\text{approx IV}}$$

where  $M$  is the molarity of sodium thiosulfate and  $V_R$  the volume of Wijs reagent used.

Alternatively, where an estimated IV is available, the weight of sample (25 ml Wijs reagent used) may be obtained from Table 3.

AnV measures the level of carbonyl compounds, particularly aldehydes, in a fat (IUPAC method 2.504). The fat, in 2,2,4-trimethylpentane solution, is treated with *p*-anisidine reagent prepared with anhydrous acetic acid. The level of reaction products is determined spectrophotometrically at 350 nm. The reagent is particularly toxic and skin contact must be

**Table 2** Relationship between SI units and other units used for peroxide value

Units of PV	Factor
Millimole active oxygen per 2 kg lipid – SI units	× 1.0
Milliequivalents of active oxygen per kilogram lipid	× 1.0
Millimole active oxygen per kilogram lipid (Lea value)	× 0.5
Milligram active oxygen per kilogram lipid	× 8.0

**Table 3** Weight of sample to be used for IV determination (25 ml Wijs reagent used)

Expected IV	Weight sample (g)	Weighing accuracy (± g)
0–5	4.0	0.0005
6–20	1.0	0.0005
21–60	0.4	0.0005
61–80	0.25	0.0001
81–130	0.15	0.0001
> 130	0.10	0.0001

avoided absolutely. Good-quality fats should show values of less than 10.

The Rancimat induction time is the time taken for a fat under test conditions to reach an approximately maximal rate of oxidation. The test is a variant of the Swift active oxygen method using a device called the Rancimat (Metrohm, Switzerland). A constant rate of air is bubbled through the fat sample held in a thermostatically controlled cell normally at 100°C. The data produced give a measure of potential shelf-life for a fat. At 100°C, a typical biscuit shortening gives a time of 50 h, cocoa butter >140 h, and sunflower oil ~12 h. The technique is reliable. All glassware must be very clean and a blank (i.e., without fat) analyzed. Samples are determined in duplicate and any showing large deviations repeated.

As part of the nutritional analysis of fat in food, it may be important to determine the level of *trans* unsaturation (TV) present. The measurement of total *trans* fatty acids is conveniently done by infrared (IR) spectroscopy but needs careful calibration with known standard solutions of pure trielaidin and tristearin (99%). Above 10% *trans*, the accuracy is good and the measurement is done on the TAGs. Below 10% *trans*, interference is common, reducing accuracy and TV is measured either by IR of the methyl esters, or, preferably by gas chromatography. Calibration in this case must also use methyl esters. The *cis* absorption is small in IR, but isolated *trans* double bonds show a relatively strong IR band absorbing at  $\sim 967\text{ cm}^{-1}$ . The AOAC published a method (AOAC 28.052–28.067) for TV. Isomerized or oxidized fats cause errors because conjugated species show strong absorption close to the isolated *trans* bond and interfere with the correct allocation of baseline. Samples and standards are usually analyzed in solution ( $200\text{ mg ml}^{-1}$ ), traditionally in carbon disulfide. A calibration line is drawn for different amounts of trielaidin mixed with tristearin, a solution of pure tristearin being in the reference beam at all times. The line should be straight. For each standard and sample record, a straight baseline is drawn joining the minima at 1000 and  $925\text{ cm}^{-1}$ . TV of samples are read from the calibration graph.

For TV analysis by gas-liquid chromatography (GLC) of fat to methyl esters (FAMEs) the official AOCS method prescribes the cyanopropylpolysiloxane phase SP2340. The column should be  $60\text{ m} \times 0.25\text{ mm}$  fused silica with a 1 m retention gap of silanized fused silica with a film thickness of  $0.2\text{ }\mu\text{m}$ . Such columns will provide adequate separation of *cis* and *trans* FAME for most situations involving food fats (except fats containing hydrogenated fish oils). However, there is peak overlap and for exacting analyses, where information is required on the iso-

meric nature of the *trans* FAME, even these columns are not adequate. For separation that is more complete, a column of SP2560,  $0.2\text{ }\mu\text{m}$  film on  $100\text{ m} \times 0.25\text{ mm}$  fused silica should be used. In both column cases, the carrier gas can be helium (linear velocity  $20\text{ cm s}^{-1}$ ) or hydrogen ( $40\text{ cm s}^{-1}$ ). Column temperature should be optimized, using standards, between 175°C and 200°C isothermal. Otherwise, faster results can be obtained by programming the temperature between 100°C and 225°C with some sacrifice to optimum resolution. The samples should be injected using the on-column technique in preference to split injection. *Cis/trans* ratios calculated from this type of chromatography will, in general, be more accurate than those obtained via IR techniques. However, this is true only below 15% *trans* content.

## Additional Analyses

GLC is applied to the analysis of fats and fat components in several ways. Typical data for GLC is shown in Table 1. This includes the analysis of FA composition after derivatizing the FAME (or propyl esters for butter fat) and the direct analysis of TAG composition. GLC is used for the analysis of sterols, hydrocarbon contaminants, pesticides, and volatile products produced during fat processing and refining.

For general FAME analysis it is adequate for most work to use wide bore ( $0.53\text{ mm ID}$ ) silica (quartz) columns. A  $30\text{ m}$  length with bonded FFAP phase (film thickness  $1.0\text{ }\mu\text{m}$ ) produces a robust column of excellent long-term stability. Other phases are suitable, such as silar 5C, silar 10C, CPSil88. Better resolution may be obtained with columns of  $0.32$  and  $0.25\text{ mm ID}$  (film thickness  $0.5\text{ }\mu\text{m}$ ) but sample loading capacity will be lower and they might be more prone to damage by mishandling (see Figures 1 and 2).

Capillary GLC columns are excellent for the analysis of TAGs. It is essential that a precolumn (retention gap) of uncoated, silanized silica tube ( $1.0\text{ m} \times 0.53\text{ mm ID}$ ) be attached to the analytical column. The injection technique of choice for both FAME and TAGs should be on-column. Split injection almost always leads to quantitative errors in these analyses. Both helium and hydrogen are adequate carrier gases. A  $7\text{--}10\text{ m}$  bonded phase (OV1, film thickness  $0.1\text{ }\mu\text{m}$ )  $0.53\text{ mm ID}$  column is used with a temperature stability of at least 350°C, but aluminum-clad columns are avoided. A temperature program is used, starting at  $\sim 100^\circ\text{C}$  rising to  $350^\circ\text{C}$  at  $\sim 10^\circ\text{C min}^{-1}$ . While the carrier gas velocity for

FAME columns should be optimal for maximum resolution, it is advantageous to have the carrier gas velocity for TAG analysis at twice optimal to minimize on-column polymerization.

Free and esterified sterols generally occur together in natural oils but are analyzed after hydrolysis as part of the nonsaponifiable fraction. To reduce chromatographic losses the sterols are derivatized to the trimethyl silyl ethers prior to GLC. Trimethylsilylimidazole is used for the preparation of TMS derivatives. A 25 m  $\times$  0.53 mm (or 0.34 mm) fused silica column with a 1.0  $\mu$ m bonded film of 5% phenyl-methyl silicone, fitted with a 1 m  $\times$  0.53 mm silanized retention gap, is adequate for good

resolution and reasonable quantitative analysis. Samples are injected using cold on-column injection. The column start temperature is 275°C with a 2 min hold, rising to 325°C at 2°C min<sup>-1</sup>.  $\alpha$ -Cholestane is used as an internal standard in this analysis.

High-performance liquid chromatography (HPLC) is routinely used for the compositional analysis of lipid classes, TAGs, and tocopherols. However, there can be problems for the quantitative detection of lipids other than tocopherols because most lipids do not have a suitable chromophore, and therefore cannot be detected spectrophotometrically. Evaporative technology such as nebulizing 'mass' detectors and the quartz/flame ionization transport system has to be employed.

For lipid class separation a 10 cm  $\times$  4 mm plain silica (3  $\mu$ m particle size) column is adequate, providing separation across the range from sterol esters and TAGs through to phospholipids and galactolipids in  $\sim$ 30 min.

For TAG separation by reversed-phase HPLC, two 10 cm Lichrosphere RP-18, 5  $\mu$ m columns are linked together. Ideally, column temperature should be kept constant at 25°C. It is advisable to analyze as many known materials as possible and construct a graph of equivalent chain length by plotting total carbon number against elution time. Peak types overlap because a double bond is almost equivalent to a chain shortening of two carbon atoms. The rather complex separation achieved yields much information about the TAG structure and is a composite of chain length and unsaturation, being more complex than the high-temperature polar phase GLC procedure. These data can be used to 'finger print' fats.

**Figure 1** FAME gas chromatography: fatty acid methyl esters of a fish oil; 30 m  $\times$  0.53 mm FFAP (see text for details). Peak names are shown as numbers separated by a colon. The number before the colon is the chain length, that after is the number of double bonds.

**Figure 2** Carbon number gas chromatography: triglycerides of a mixture of 1:1 butter fat and cocoa butter; 8 m  $\times$  0.53 mm OV1 (see text for details). Peak names are shown as carbon numbers which are the sum of the carbons in the three fatty acid chains, excluding the glycerol carbons.

For chocolate fats in particular, it is often necessary to know the composition of the TAGs based simply upon the level and position of unsaturation. The SOS (1-saturated, 2-monounsaturated, 3-saturated) type TAGs are responsible for the particular physical properties of cocoa butter and its equivalents. The information can be obtained from the reversed-phase method mentioned above, but a simpler profile is obtained by using 5% silver nitrate-impregnated silica as a 25 cm column.

Tocopherols are analyzed in their unesterified form and separations are very easy by HPLC. The use of fluorescence detection provides very accurate results. The oil is diluted with eluent (3% tetrahydrofuran in isooctane) to  $\sim 10 \text{ mg ml}^{-1}$ . Pure standards are analyzed ( $2 \mu\text{g ml}^{-1}$ ) to obtain retention data, while pure  $\alpha$ -tocopherol is used as an external standard for every two samples. A 15 cm column of 5  $\mu\text{m}$  Chromegasphe is equilibrated with the isocratic solvent at  $1.5 \text{ ml min}^{-1}$ . Injection volume is 50  $\mu\text{l}$ . The spectrofluorimeter excitation is 290 nm and emission is 330 nm. Full separation should be readily achieved, but the column will require conditioning by pumping chloroform-methanol (2:1; v/v) for 10 min every 30 samples. After this conditioning, the column activity must be regenerated by pumping normal eluent for at least 20 min.

well as being good sources of dietary fiber, mineral salts, and vitamins, especially vitamin C. The organic acids found in fruits essentially balance with the sugars to give them their characteristic flavors and are therefore also a vital component.

## Introduction

Fruits have long been valued as a foodstuff owing to their pleasant flavor and aroma, and attractive appearance; however, the use of fruits as a staple in the diet has only become possible in the past century through the development of canning and other bulk preservation techniques, and improvements in transportation and storage systems. The increased awareness of the importance of a nutritionally balanced diet has also contributed to the increased consumption of fruit and fruit products.

Fruits are an important low-fat energy source containing varying proportions of sugars and starches as

## Major Components

The major component of fresh fruit is water, with levels ranging from 65% (in avocado) to 93% (e.g., in melons, strawberries). Dried fruit products can contain up to 25% water while fruit juices can vary between 85% and 93%. The second most important component in terms of percentage content is carbohydrate, with reducing sugars, primarily a mixture of glucose and fructose, being the main soluble carbohydrate. Most fruits contain relatively low levels of sucrose; however, it is the primary sugar in peaches, apricots, bananas, pineapple, and certain citrus fruits. Starch, cellulose, hemicellulose, and pectin are also found in varying proportions in fruit.

In general, fruits are poor sources of protein and lipid, the major exceptions to this being avocado and olives, which can contain ~11% and between 10% and 40% lipid, respectively.

Most fruits are particularly rich in organic acids, the principal ones being citric, tartaric, and malic acids; however, the range is extensive.

By far the most important acid present in fruits is L-ascorbic acid, vitamin C. Fruits, together with vegetables, are the main sources of this vitamin in the human diet. Its importance was first reported by a Hungarian physician in 1732, who documented the relationship between citrus fruit and antiscorbutic activity. The concentration of L-ascorbic acid can vary between only 2 and 30 mg per 100 g in apples and pears, to over 1000 mg per 100 g in rose hips and certain cherry varieties. The majority of fruits, however, including citrus, have values in the region of 30–100 mg per 100 g. Today, orange juice alone provides 60% of the US Recommended Daily Allowance (RDA) for vitamin C in the American diet.

Several fruits are good sources of  $\beta$ -carotene, for example, apricots, peaches, melons, and cherries, while a range of B vitamins (pantothenic acid, folic acid, biotin, thiamine, and riboflavin) can also be found. In general, however, the concentrations of the latter vitamins are low when compared with other animal and vegetable sources.

Fruits and fruit products contain a wide range of mineral salts including potassium, calcium, magnesium, phosphorus, and the trace elements, copper, zinc, iron, and manganese, with potassium being the most abundant of these in a majority of fruits. Whereas a serving of a fruit or fruit product may provide only a small percentage of the RDA of many of these mineral nutrients, they are still good sources when calculated in terms of their calorific contribution.

## Sampling and Preparation for Analysis

Sampling and preparation techniques are the first, and some of the most important, steps toward achieving an accurate analytical result. There are many sources of error in any analytical technique, e.g., analyst's error, contaminated reagents or equipment, inappropriate methodology, and calculation or data handling error. Most of these can be controlled or detected by the use of standards, blanks, reference samples, and other quality control procedures. An unrepresentative sample, however, may not be so easily detected. Foodstuffs are naturally heterogeneous materials and, therefore, obtaining a homogeneous and representative sample is a major problem. For most fruits and fruit products sampling

will be carried out from bulk materials. For such sampling it is important, first, to identify the size of the population or batch, then to select and remove gross samples from this population, and finally to reduce these samples to a suitable laboratory sample size, all whilst maintaining as far as possible the representative nature of the sample. This is generally achieved by selecting several samples from the bulk, either randomly or according to a plan, and thoroughly mixing these to form a composite sample from which a subsample for laboratory analysis can be taken.

There is much information available on sampling plans for foodstuffs. The Codex Alimentarius Commission (document CAC/RM 42-1969) deals with sampling plans for prepackaged foods, and there are standards available from the International Standards Organization (ISO) for sampling of various foodstuffs including fresh fruits and vegetables (ISO 874:1980). Details of the mathematical principles involved are dealt with in many books on statistics.

Due both to the economic aspects of statistical sampling plans and the difficulties encountered owing to the natural variation in foodstuffs, most analyses, however, are carried out on randomly selected samples.

The method of preparation used to produce a homogeneous laboratory sample varies considerably with food type. Examples of laboratory sampling and preparation procedures for fresh fruit products can be seen in **Table 1**.

There is a wide range of fine-slicing devices available that are suitable for homogenization of fruit and fruit products: liquidizers, domestic-type food processors, Waring blenders. Care must be taken to ensure that excessive heat generation does not occur during the homogenization process that can lead to loss of moisture, and that the sample is transferred immediately to a suitable storage vessel. These should be of glass or rigid plastic, have a tightly fitting lid and be easily labeled.

Stabilization of the product after preparation is also an important consideration, with the sample susceptible to change due to enzymatic, oxidative, or microbial action. In most cases for fruit and fruit products the most practical way of achieving this is by rapid freezing and storage at  $-20^{\circ}\text{C}$ . Inactivation of enzymes can also be achieved by treatment with 80% methanol or ethanol, or ice-cold 10% perchloric or trichloroacetic acid, while oxidation may be reduced if reducing agents such as hydrogensulfite or dithiothreitol are added during the homogenization process. The most appropriate method will depend on the analyses to be performed and the exact nature of the sample.

**Table 1** Preparation procedures for fresh fruit products

<i>Fruit type</i>	<i>Preparation technique</i>
Apples, pears, etc.	Select 10–15 fruits Remove extraneous matter: leaves, stalks, etc. Cut into quarters along the longitudinal axis Take a selection of the quarters and mechanically finely chop and mix
Plums, peaches, apricots, etc.	Select 15–20 fruits Remove extraneous matter and destone Proceed as for apples, pears, taking care to collect any released juices
Berries, cherries, olives, etc.	Remove a random selection of individual berries from the sample (minimum of 100 g) Remove stones (preferably using a cherry stoner) while carefully avoiding loss of juice and fruit flesh Mechanically finely chop and mix
Exotic fruits: bananas, avocados, kiwi, etc.	Remove inedible portions: skin, peel, stones, etc., and extraneous matter Cut into quarters Take a selection of these quarters and mechanically chop and mix
Citrus fruits: oranges, grapefruit, lemon, lime, etc.	

## Analytical Methods

### Moisture/Total Solids

Water is present in foods as both bound and available free water, the quantification of which is dependent on the methodology used.

The standard procedure for measuring moisture in fruits and fruit products is by weight loss on drying. References to this methodology can be found in many books; however, they all follow the same basic technique, i.e., Association of Official Analytical Chemists (AOAC) methodology:

Accurately weigh a sample into a large flat-bottomed dish and dry at 70°C under vacuum (pressure  $\leq 100$  mmHg) until consecutive weighings vary by less than 3 mg.

This method has the disadvantage of a considerable drying time (usually 4–6 h) and many rapid techniques are now available. Infrared drying ovens and microwave ovens have been shown to produce comparable results to vacuum oven drying methods for various fruit products. Nondestructive techniques such as low-resolution nuclear magnetic resonance

(NMR) and near-infrared (NIR) spectroscopy can also be used for moisture determination and are of particular use for online checking during food manufacture and processing.

### Carbohydrates

**Sugars** A wide range of methods is available for the determination of sugars in fruit and fruit products. These include relatively simple refractometry and hydrometry techniques, polarimetry, copper(II) reduction, enzymatic/color detection, and various chromatographic techniques. These vary greatly in their sensitivity, specificity, and in the level of equipment and expertise required, and these considerations generally dictate the method chosen.

**Refractometry** This allows for the rapid, reasonably accurate estimation of sugar levels based on the measurement of soluble solids. Correction tables exist allowing for other dissolved substances, e.g., acids, and for changes in temperature; however, many modern refractometers make automatic allowance for this.

**Hydrometry** This technique relies on the measurement of relative density but is generally less accurate than refractometry.

**Polarimetry** The determination of sucrose and reducing sugars in fruit and fruit products by polarimetry is an AOAC recommended method. The polarimeter measures the rotation of plane polarized light caused by a solution containing an optically active compound. Separate measurements for the quantification of sucrose and reducing sugars can be made with the Clerget–Hertzfeld double-polarization method.

**Copper(II) reduction** These methods rely on the ability of certain sugars, i.e., all monosaccharides and the disaccharides maltose and lactose, to act as reducing agents, owing to the presence of free aldehyde or ketone groups in their structure. Fehling's solution consists of alkaline copper(II) tartrate and it is the ability of reducing sugars to convert this to insoluble copper(I) oxide that forms the basis of a number of analytical procedures. The most widely accepted of these are the Lane and Eynon method, which has a titrimetric endpoint using a redox indicator and the Munson and Walker method (AOAC) where the copper(I) oxide is filtered off and weighed. The Luff–Schoorl method uses alkaline carbonate solution and sodium citrate and employs an iodimetric determination of the excess copper(II) with

thiosulfate. This method is recommended by the Codex Alimentarius Commission for the analysis of fruit juices.

All of the copper reduction methods can be used to determine sucrose, after inversion (conversion to glucose and fructose), as well as reducing sugars. These methods are therefore particularly suitable for fruits and fruit products.

**Liquid chromatography (LC)** LC is now a popular and useful analytical technique that has the advantage that different sugars can be determined simultaneously. The separation technique can be carried out using strong cation-exchange chromatography, or a modified silica gel-amino column, with detection by refractometry. This method does have certain disadvantages in that initial equipment costs are high and, owing to the sensitivity of the detectors, they are best when used exclusively and continuously for the same analysis. The latest development in LC analysis of carbohydrates uses improved anion-exchange techniques combined with pulsed amperometric detection, which is both more sensitive and specific than the traditional LC methodology.

**Gas chromatography (GC)** This technique has the advantage of allowing food sugars to be determined with very high sensitivity and provides an AOAC recommended method. The sample sugars have to be converted to volatile and heat-stable derivatives before analysis and this technique is not widely used in routine analysis because of the accuracy and relative simplicity of alternative methods.

**Enzymatic reactions** Enzymatic reactions have the advantage of being specific; for example, hydrolysis of sucrose is more accurate using invertase than an acid. A wide range of sugar analysis kits is available commercially; for example, sucrose/glucose/fructose kits are particularly suitable for fruit and fruit products. They, in common with the copper reduction methods, have the advantage of simple sample preparation techniques. The enzymatic reactions involved cause the reduction of  $\text{NADP}^+$ , the concentration of which is determined by spectrophotometry at 340 or 366 nm. Great care is needed in their use because of the very precise quantities involved; however, the results obtained compare favorably with more traditional methods and the methods are now widely accepted.

**Starch** The determination of starch in fruits and fruit juices is normally achieved by the hydrolysis of the starch to glucose and the subsequent analysis of glucose levels. Acid hydrolysis methods can be

subject to error because of the possibility of hydrolysis of nonstarch polysaccharides or the destruction of glucose. Enzymatic hydrolysis of the starch can also be employed using amyloglucosidase, and commercial kits are available that allow for concurrent analysis of the prepared sample for glucose content, with and without the addition of the amyloglucosidase.

**Dietary fiber** The determination of dietary fiber has increased greatly in importance in recent years; however, due partly to lack of a clear definition for dietary fiber, several standard methodologies exist.

**AOAC enzymatic gravimetric method** The samples are dried, with fat extracted if necessary, gelatinized with heat-stable  $\alpha$ -amylase, and enzymatically digested with protease and amyloglucosidase to remove protein and starch. The soluble dietary fiber is then precipitated using ethanol, the residue filtered and washed, and corrections are made for indigestible protein and ash. This method is widely used in the EC and the USA.

**Englyst method** Samples are defatted if required and any starch present is gelatinized and removed by enzymatic digestion. The remaining polysaccharides are hydrolyzed by sulfuric acid and the resulting sugars can be measured either colorimetrically or by using gas chromatography. This method can be used to determine both total nonstarch polysaccharides and resistant starch, and is a recognized method in the UK and Canada.

**Pectin** There are many methods for the estimation of pectic substances. The most commonly used for fruit products are those based on aqueous extraction, saponification with cold alkali, acidification and the precipitation of the pectin as the calcium salt; alternatively, precipitation using acetone or alcohol can be utilized.

### Minerals: Sodium and Potassium

The AOAC and Codex recommended methods for determination of potassium and sodium are by flame atomic emission spectrometry. These methods have the advantage of quick and simple sample preparation, aqueous dilution of sample and filtration, with rapid, reasonably accurate detection. The samples can be aspirated directly into the flame and the readings quantified by comparison with a range of known standards. Atomic absorption spectrometry can also be used, giving increased accuracy and low-level sensitivity and a far wider range of detectable

minerals. It has the disadvantage of higher equipment costs and requires a dry-ashing sample preparation technique, which, though simple, can take a relatively long time; however, if trace metals or other minerals are also being determined the ashed sample can be used for all analyses.

### **Vitamin C**

There are two standard (AOAC) procedures for vitamin C (ascorbic acid) determination in fruits and fruit products. The sample preparation is common to both and involves maceration/dilution of the sample in a stabilizing solution such as 5% metaphosphoric acid or trichloroacetic acid followed by filtration. The ascorbic acid can then be determined by titration with 2,6-dichloroindophenol, where the ascorbic acid reduces the redox indicator dye to a colorless solution, or by fluorimetric detection, in which the ascorbic acid is oxidized to dehydroascorbic acid, which then reacts with *o*-phenylenediamine to produce a fluorophore. The latter method has the advantages that it is suitable for colored solutions and can also be used to measure levels of naturally occurring dehydroascorbic acid as well as ascorbic acid. Many other methods are available for determination of vitamin C, with the use of LC techniques currently the subject of much interest. Reversed-phase LC techniques can be used to determine both dehydroascorbic acid, ascorbic acid and their isomers.

### **Phosphate**

The sample is first ashed and dissolved in hydrochloric acid; the phosphate can then be determined titrimetrically or colorimetrically. The most widely accepted method is a colorimetric method using Mison's reagent, which is based on the reaction between the acidified sample solution and an acid reagent containing molybdic acid and vanadic acid, to produce the stable orange-yellow vanadomolybdophosphoric acid.

### **Organic Acids/Acidity**

For routine analysis a measurement of titratable acidity is usually sufficient, with the acidity of the fruit/fruit product calculated as the predominant acid, e.g., as citric acid in citrus fruits, as malic acid in apples. The sample is diluted in distilled water and titrated against dilute sodium hydroxide to either a phenolphthalein endpoint or to pH 8.10. Volatile acidity, generally expressed as acetic acid, can be measured by distilling the sample using a steam distillation apparatus, with titration of the distillate as above. Individual acids can be determined using a

range of techniques including chromatographic and titrimetric methods fully described by the AOAC, and enzymatic methodologies with commercial enzyme-based test kits now available for many fruit acids. LC techniques are also available facilitating identification and quantification of a range of organic acids.

## **Quality Assurance of Fruits and Fruit Products**

Many analyses and tests are carried out on fruits and fruit products as a means of quality assurance and many regulations and specifications exist in relation to this. These include the Joint Food and Agriculture Organisation of the United Nations/World Health Organization (FAO/WHO), Food Standards Programme-Codex Alimentarius, the US Department of Agriculture (USDA) standards for grades of processed fruit products, the UK Fruit Juices and Fruit Nectars Regulations, and EC directives.

The range of chemical analyses carried out to determine compliance with quality and specification requirements can include: pH, titratable, and volatile acidity; total solids, soluble solids ( $^{\circ}$ Brix), water-insoluble solids, sugars; acid-insoluble ash, alkalinity of ash, mineral impurities, trace metals (tin, copper, zinc, iron, aluminum), heavy metals, e.g., lead; ethanol; preservatives such as sulfur dioxide, sorbic acid, benzoic acid, and benzoates.

Many specifications also define standards for physical characteristics, e.g., color, flavor, appearance, and defects. These are generally assessed by trained personnel; however, a range of equipment is available for color measurement.

Many of the chemical analyses used for quality assurance have already been discussed; however, there are other important tests worth brief consideration.

### **Essential Oils**

Citrus juices make up the bulk of the retail fruit juice market, with citrus essential oil being one of the primary constituents contributing to the flavor of the juice. Both the Codex and USDA standards legislate an essential oil content, the official method for determination of the recoverable oil being the Scott Oil Method.

### **Ethanol**

Low levels of alcohol, which can result from the fermentation of juices, are permitted in the Codex standards; however, they must be monitored. The levels can be determined using distillation and

dichromate oxidation methodology, enzymatic methods, and GC, with the last now widely accepted.

### Mold Contamination

The Howard mold count is the traditional method for assessing mold content in tomato products, but has also been applied to other fruit products. The samples are studied microscopically using a Howard cell and the number of positive fields, those where the aggregate length of not more than three mold filaments exceeds one-sixth of the diameter of the field, is counted. There are regulations governing the percentages of positive fields that are acceptable in the various products. The *Geotrichum* mold count method suitable for citrus juices, canned fruits and juices, and pureed fruit products is also used.

### Preservatives

Many of the standards governing fruit and fruit products contain guidelines on acceptable levels of preservatives, e.g., sulfur dioxide, benzoic acid/benzoates, and sorbic acid.

Sulfur dioxide (SO<sub>2</sub>) is generally measured using indirect methods. The AOAC describes a modified Monier Williams method, while the Codex standards and EC directive recommend the Tanner modified method. Both are based on similar principles, involving the distillation of the SO<sub>2</sub> from an acidified aqueous suspension of the food. The evolved gas is subsequently trapped in hydrogen peroxide where it reacts to form sulfuric acid which is then titrated against dilute sodium hydroxide.

Benzoic acid and sorbic acid can both be extracted using modified Monier Williams distillation methods and quantified spectrophotometrically, or in the case of benzoic acid using thin-layer chromatography (TLC). LC and GC methodologies are now available and routinely used, having the advantage of simultaneous quantification of both benzoic acid/benzoates and sorbic acid.

### Trace Metals

Trace metals present in foods can have nutritional or toxicological significance and in the case of certain metals, e.g., copper and zinc, both of these. Fruit products are routinely tested for trace metal contents, e.g., canned fruits for tin, iron, copper, and zinc; fruit juices for copper, zinc, and lead; tomato puree for copper and also lead, tin, and arsenic. Statutory limits exist for many metals, e.g., lead, arsenic, zinc, and copper. Atomic emission spectrometry is now widely used for trace metal analysis as multielement determinations can be made on a single sample; however, other methodologies are

applicable. AOAC details colorimetric methods for determination of copper as diethyldithiocarbamate, with colorimetric methods for tin also available.

### Chemical Residues

Fresh fruit in particular may also be analyzed for the presence of chemical residues. These may be present due to specific horticultural and agricultural practices (pesticides, herbicides, etc.), environmental contamination, or through use of certain permitted additives. Detection and quantification of these residues is a complex analytical problem. Most methods used are based on solvent separation coupled with chromatographic determination using LC, GC, or GC-mass spectrometry.

### Added Colors

Fresh fruits must not contain any added color; however, certain colors are permitted in processed products. The range and use of colors are strictly governed, e.g., by UK and USDA regulations, and EC directives. Many methods exist for the extraction, separation, and identification of colors. A standard method suitable for fruit juices and other products involves the separation of colors from an acidified aqueous solution of the food using reversed-phase C<sub>18</sub> cartridge and identification using TLC or UV-visible spectrophotometry by comparison with standard color solutions.

### Adulteration

By far the largest area of adulteration occurring in fruit and fruit products is in relation to fruit juices. The size and value of the fruit juice market has meant that falsification of juice has become a lucrative business. The main areas of juice adulteration are the addition of water, sugar and water, or other fruit-derived products. Water addition is most effective when used in single-strength juices, as concentrates have to be diluted to a certain Brix value to meet specifications. The addition of sugar and water is difficult to detect, because of the possibility of adding appropriate sugar mixes to duplicate natural proportions. The addition of other constituents, e.g., organic acids, minerals, amino acids, carotenoids, to maintain the chemical balance of the fruit juice further complicates detection. The most complex form of adulteration is the use of materials derived from fruit but which cannot legally be used in the fruit juice. This can range from the addition of other fruits, to the use of peel extract, pulp wash, and the water extract of rag, pulp cell membranes, seeds, etc., in citrus juices. The wide range of fruit-derived

materials available with different properties can be combined in such a way as to make detection extremely difficult.

The methods available for detecting adulteration can be divided into two types: those which detect a specific indicator of the added material and those which rely on the disturbance of a natural analytical balance.

### **Stable Isotope Analysis**

The ratios of stable isotopes in biological materials provide a valuable tool for the analyst in detecting adulteration.

**Carbon isotope ratios** The ratio of the carbon isotopes ( $^{13}\text{C}/^{12}\text{C}$ ) in plant sugars varies according to whether the plant has a  $\text{C}_3$  or  $\text{C}_4$  photosynthetic carbon cycle. Most fruit juices, including citrus and apple, are derived from plants with  $\text{C}_3$  metabolism; however, cane sugar, corn invert sugar, and high fructose corn syrup all originate from the less common  $\text{C}_4$  plants.

**Oxygen isotope ratios** The use of oxygen isotope ratios is largely restricted to the measurement of water in fruit juices. Water in fruit is assimilated from groundwater and reflects the isotope ratios present in it; variations between juices are therefore naturally derived from variations in the groundwater. Analysis for carbon and oxygen isotopes is carried out using mass spectrometry; however, analysis is not simple.

**Hydrogen isotope ratios** The ratio of  $^2\text{H}/^1\text{H}$  can provide information on water addition but can also detect the addition of sugars from other plants. Measurement is usually carried out by the formation of sugar derivatives, which eliminates the oxygen-bound hydrogen from the molecule. This is most simply achieved by the fermentation of the sugars to ethanol. Fourier transform NMR spectroscopy has been used to examine the internal  $^2\text{H}/^1\text{H}$  ratios in the ethanol and has been successful in the detection of beet sugar in orange juice.

**Oligosaccharide analysis** The technique is based on the detection of specific oligosaccharides that are not normally present in the juice but are introduced by the addition of sugars that have undergone inversion. Analysis relies upon liquid chromatographic detection.

### **Analytical Pattern Methods**

There are several analytical systems that rely on authentic juice having a consistent pattern based on its composition.

**Matrix method** This method relies primarily on sugar profiles, UV-visible spectrofluorimetry, metals, calcium stable isotopes, and flavanoid glycosides to detect the addition of sugar, other fruits, or pulp wash.

**RSK system** This, the best known of the analytical systems, was developed in Germany in 1977 and is used to control commercial practice in that country. RSK stands for Richtwerte und Schwankungsbreiten Bestimmter Kennsahlem, or guide values and ranges of specific reference numbers. The juices are analyzed for a very broad range of analytes for which guide values, the ranges, and central value are given. Because of the natural variation in juice composition the ranges given are necessarily broad, and the detailed interpretation of the analytical data is an integral part of the system.

Other systems also exist including the French national system, the AFNOR standards, and on a European basis, the Association of the Industry of Juices and Nectars from Fruits and Vegetables of the European Economic Community has drawn up accepted analytical characteristics or reference standards.

**Visible and ultraviolet spectra** The use of visible and UV absorption and fluorescent spectral characteristics to detect juice adulteration has also been developed, with the presence or absence of specific absorption maxima at selected wavelengths indicating adulteration.

**Prospective methods** Several new techniques for the detection of fruit juice adulteration are still under development. These include pyrolysis mass spectrometry, size-exclusion chromatography, NIR spectrometry, and an expert system for data interpretation. With the methods of falsifying juices being so numerous and diverse, however, it is unlikely that any single method will ever be capable of detecting all forms of falsification.

## Introduction

Analytical measurements on food packaging materials are generally carried out for three main purposes:

- To identify the components of the packaging.
- To identify and measure substances present that could migrate into the packaged foods and cause a health hazard to the consumer of the food. This work is often accompanied by measurements of the migration of particular substances into either the actual packaged foods, or into food simulants.
- To identify and measure substances present that could migrate into the packaged foods and result in adverse effects on the organoleptic properties, such as taste or odor.

## Food Packaging Materials

The main categories of basic materials used for food packaging are:

- plastics,
- regenerated cellulose films,
- paper and board,
- metal, and
- glass.

Of these, plastics are the most widely used and within this category there are also the largest numbers of variants. Many packaging materials are, however, multilayered with either different layers of plastics or combinations of plastics with paper/board, metal, or

glass. The individual properties of the different materials are used to produce food packaging with the required characteristics. For example, in a packaging material with two layers of different plastics, one layer might provide the basic strength whilst the other layer enables the packaging to be easily heat-sealed. Coatings are also often added to the basic plastic packaging material to provide additional barriers to the permeation of oxygen and water vapor. These coatings can be polymeric or vacuum deposited aluminum.

With some metal cans used for foods and beverages there is an inner lacquer (plastics) coating for the purpose of either preventing corrosion of the metal by the food/beverage, or preventing contamination of the food/beverage by the can metal.

A combination of a polymer layer with a board is used to package liquids such as milk, where the plastic layer provides the barrier to contain the milk within the package and the board the basic strength. Where it is necessary to store the beverage for long periods, such as fruit juices, additional barrier properties are required to prevent permeation of oxygen into the food product. To achieve this additional protection, an aluminum layer is incorporated within a plastic/board composite.

With many of the multilayer packaging materials adhesives are used to bind the layers together. The printing on the outside is a further important component of food packaging.

## Identifying the Components of Packaging Materials

It is often necessary to identify or confirm the basic composition of the packaging materials. This applies particularly with plastics due to the range of polymer types that are used. Six major polymer types are used for packaging and these are shown in Table 1, with

## Introduction

Analytical measurements on food packaging materials are generally carried out for three main purposes:

- To identify the components of the packaging.
- To identify and measure substances present that could migrate into the packaged foods and cause a health hazard to the consumer of the food. This work is often accompanied by measurements of the migration of particular substances into either the actual packaged foods, or into food simulants.
- To identify and measure substances present that could migrate into the packaged foods and result in adverse effects on the organoleptic properties, such as taste or odor.

## Food Packaging Materials

The main categories of basic materials used for food packaging are:

- plastics,
- regenerated cellulose films,
- paper and board,
- metal, and
- glass.

Of these, plastics are the most widely used and within this category there are also the largest numbers of variants. Many packaging materials are, however, multilayered with either different layers of plastics or combinations of plastics with paper/board, metal, or

glass. The individual properties of the different materials are used to produce food packaging with the required characteristics. For example, in a packaging material with two layers of different plastics, one layer might provide the basic strength whilst the other layer enables the packaging to be easily heat-sealed. Coatings are also often added to the basic plastic packaging material to provide additional barriers to the permeation of oxygen and water vapor. These coatings can be polymeric or vacuum deposited aluminum.

With some metal cans used for foods and beverages there is an inner lacquer (plastics) coating for the purpose of either preventing corrosion of the metal by the food/beverage, or preventing contamination of the food/beverage by the can metal.

A combination of a polymer layer with a board is used to package liquids such as milk, where the plastic layer provides the barrier to contain the milk within the package and the board the basic strength. Where it is necessary to store the beverage for long periods, such as fruit juices, additional barrier properties are required to prevent permeation of oxygen into the food product. To achieve this additional protection, an aluminum layer is incorporated within a plastic/board composite.

With many of the multilayer packaging materials adhesives are used to bind the layers together. The printing on the outside is a further important component of food packaging.

## Identifying the Components of Packaging Materials

It is often necessary to identify or confirm the basic composition of the packaging materials. This applies particularly with plastics due to the range of polymer types that are used. Six major polymer types are used for packaging and these are shown in Table 1, with

**Table 1** Types of plastics used for food packaging and typical uses

<i>Plastic type</i>	<i>Typical uses</i>
Polyethylene	Bags and bottles
Polypropylene	Wrapping films and pots
Poly(vinyl chloride), unplasticized	Trays, bottles, and containers
Poly(vinyl chloride), plasticized	Wrapping film and cling film
Polystyrene	Trays, pots, and containers
Poly(ethylene terephthalate)	Lidding films and oven containers
Polyamide (nylon)	Laminated with polyethylene, 'boil-in-bag' pouches

typical uses. In addition to these basic polymer types, various copolymers are also used. For example, ethylene is copolymerized with vinyl acetate to produce ethylene vinyl acetate, styrene is copolymerized with both acrylonitrile and butadiene to produce the terpolymer ABS.

On simple, one- or two-layer structures, identification of the polymer type is conveniently achieved using Fourier transform infrared spectroscopy (FTIR). Each of the major polymer classes or copolymers has unique infrared spectra and are easily identified by comparison of the spectra to reference spectra.

The infrared spectrum of a plastic packaging material is most easily obtained when the sample is in the form of a film sufficiently thin to allow the infrared spectrum to be obtained through the film. However, with most plastic packaging, even those that are used in the form of films, the thickness is usually too great to obtain a good transmission spectrum. With some film materials stretching can adequately reduce the thickness. Alternatively, it may be possible to produce a solvent solution and cast a film of the required thickness. Thin films may also be pressed from the sample by careful melting on a hot-plate. Caution should be exercised with melt pressing, as apart from polymer degradation, there is the risk of altering the structure, for example, by skewing a polymer layer away from the region of analysis.

Infrared spectra may be obtained from surfaces using a variety of techniques. These included attenuated total internal reflectance (ATR) and specular and diffuse reflectance. These techniques involve the infrared beam passing through only the outer few micrometers of the sample. The most widely applicable is ATR. A typical two-layer plastic material used for lidding on plastic food trays consists of polyethylene and poly(ethylene terephthalate) bound together with an adhesive. ATR infrared spectra of the two surfaces will easily identify one surface as

polyethylene and the other surface as poly(ethylene terephthalate) by the very different spectra obtained. With the standard KRS5 (thallium bromide/iodide) ATR crystal the depth of penetration of the infrared radiation is a few micrometers. This is less than the individual polymer layers and consequently the adhesive is not 'shown' in either of the ATR spectra.

Where the polymer material is a copolymer it is often possible to obtain a measurement of the relative amounts of the various monomer components from an infrared spectrum. For example, with an ethylene-vinyl acetate copolymer the relative heights of absorption bands from both the ethylene and vinyl acetate are measured and ratioed with the spectrum recorded in the absorbance mode. The most convenient absorbance bands are:  $720\text{ cm}^{-1}$  for polyethylene and  $1235$  or  $1740\text{ cm}^{-1}$  for vinyl acetate. Copolymers of known composition are required for calibration. It is possible to obtain an assessment on the butadiene and acrylonitrile contents in styrene/butadiene/acrylonitrile copolymers. The bands usually used are: for styrene  $1600\text{ cm}^{-1}$ , for acrylonitrile  $2240\text{ cm}^{-1}$ , and for butadiene  $996\text{ cm}^{-1}$ .

Modern packaging materials are very often multiple-layered structures. If the packaging material is a laminate or coextrusion each layer will produce an infrared spectrum. The resulting composite spectrum becomes difficult to interpret. In most cases laminates are manufactured using adhesive to bond the layers together. It is sometimes possible to select a solvent to dissolve the adhesive thereby enabling the individual polymer layers to be separated. The separated polymers can then be identified by their infrared absorption spectra. Spectra from a polyethylene/poly(ethylene terephthalate) laminate and the separated layers are shown in **Figures 1A–1D**. Polyurethane-based adhesives are widely used to bond poly(ethylene terephthalate) to polyolefins. Hot benzylalcohol is a good solvent for a range of polyurethanes. Other solvents include tetrahydrofuran and chloroform for acrylate-based adhesives. This approach also enables the adhesive to be identified.

An approach that can be applied to laminates and coextrusions is to selectively dissolve and remove polymer layers by careful selection of solvents. Thus, the nylon layer in a polyethylene/nylon/polyethylene coextrusion can be isolated by boiling in xylene. Alternatively, the nylon could be removed by boiling in formic acid. Solvents for the selective removal of polymers are listed in **Table 2**. Acids or alkalis should be avoided on some polymers where there is a risk of reaction with the polymer. An example would be the use of concentrated sodium hydroxide solution on a metallized film comprising certain acrylic/ethylene

**Figure 1** Infrared transmission spectra of: (A) polyethylene/poly(ethylene terephthalate) laminate; (B) separated poly(ethylene terephthalate) layer; (C) separated polyethylene layer plus adhesive; and (D) separated polyethylene layer with adhesive removed.

**Table 2** Solvents for plastics

Plastic type	Solvents
Polystyrene and copolymers	Chloroform, ethyl acetate, ketones
Polyethylene	Decalin, hot toluene
Polypropylene	Decalin, hot xylene
Poly(vinyl chloride)	Tetrahydrofuran, cyclohexanone
Poly(ethylene terephthalate)	<i>o</i> -Chlorophenol, trichloroacetic acid
Polyamide	Formic acid, phenols

ionomer types, where marked alterations to the infrared spectra can result from such treatment.

It is sometimes difficult to obtain thickness measurements on layers due to swelling of layers with the solvent or partial break up of thin layers. If the density of the polymer is known or measured the thickness of a layer may be calculated from the weight of the polymer.

Although infrared spectroscopy is a useful technique for identifying polymers in packaging materials it is important to emphasize that as a result of the development of packaging technology, it is now

rarely possible or wise to use the technique on its own without recourse to other analytical techniques. There has in recent years been a trend toward the use of coextrusions, and away from adhesive bonded laminates. Coextrusions of a wide range of polymers can be produced using thin tie layers (a few micrometers) of polymer with compatibility for the different polymer types. For example, polypropylene and ethylene vinyl alcohol can be extruded into films and bottles. Layers within coextrusions cannot be readily separated using solvents. In addition, the time and cost constraints upon the analysis of coextrusions mean that physical isolation of layers is often impractical.

The most efficient approach to establishing the structure of packaging is a combination of optical microscopy, differential scanning calorimetry (DSC), and infrared spectroscopy. The first stage in establishing the construction of an unknown packaging material is to subject it to the following optical microscopy techniques. A section (typically 5–10  $\mu\text{m}$ ) is cut from a 10  $\times$  10 mm area using a microtome. It is important that the sample is held rigid but strain free and cut with a very sharp knife. The best knife for packaging material is usually a freshly made glass

knife. Thicker sections ( $>2\text{ mm}$ ) require use of a steel knife. It is sometimes beneficial to cool samples below their glass transition temperature ( $T_g$ ) in order to provide a more rigid structure to section. It may also be necessary to mount samples in potting resin for support prior to sectioning through the sample and resin.

The section is then examined under polarized light (using cross-polars). A tint plate is useful to provide color differentiation of layers. This enables the number and thickness of each layer to be established. Thickness measurements are made by calculation after measuring the total thickness of the sample using a micrometer. The ratio of total thickness to layer thickness is calculated in arbitrary units using the scale graduations on the microscope. The thickness of each layer is then calculated from the ratios knowing the true total thickness. An example of a typical cross-section of a coextrusion is shown in Figure 2.

Information on the composition of individual layers in the structure can then be obtained by observations of the layer under the microscope. Different types of polymers have a recognizable morphology. Polypropylene has very large spherulites distinct from many other polymers. Figure 3 shows a photograph obtained from polypropylene cooled slowly from a melt. Compounded poly(vinyl chloride) (PVC) can also be quite characteristic due to the different phase regions arising from the presence of impact modifiers as well as pigment specks from color adjusters. Calcium carbonate filler and talc anti-blocking agent have recognizable morphologies. It is also possible to determine whether a layer contains

recycled process scrap. It is quite common for off-cuts to be recycled in an inner layer of a coextrusion.

Infrared spectra are then obtained from the surfaces of the packaging material after solvent removal of any print or lacquer. Spectra are best obtained by ATR. A further portion of the packaging material is then subjected to DSC. This is a technique where a few milligrams of the sample is subjected to a programmed temperature ramp in a specified atmosphere inside a sample chamber. The heat flow (power) to the sample is monitored against temperature as the sample is subjected to the heating ramp. For the purposes discussed here this provides a trace showing the melting points of the polymers present. Typical melting ranges for common packaging polymers are tabulated in Table 3.

The technique cannot be used to obtain melting points for amorphous polymers. The sample polymer is heated and cooled and then reheated at a controlled rate to record the melting points. This procedure removes hysteresis effects that may be present in the polymer as a result of the manufacturing process and which may alter the perceived melting point. DSC is capable of identifying polymers and polymer blends

**Figure 2** Cross-section of a coextrusion viewed through a tint plate on an optical microscope. PET = Poly(ethylene terephthalate), (LD-MD) PE = ? (Reprinted with permission from Mr R Musgrove, Pira International.)

**Figure 3** Polypropylene spherulites viewed through a tint plate. (Reprinted with permission from Mr R Musgrove, Pira International.)

**Table 3** Typical melting ranges for common polymers

Polymer	Melting range ( $^{\circ}\text{C}$ )
Linear low-density polyethylene	115–130
Low-density polyethylene	100–115
Ethylene vinyl acetate	100–110
Polyamide	210–260
Poly(ethylene terephthalate)	240–260
Poly(vinylidene chloride)	220
Polypropylene	160–170
Ethylene propylene random co polymer	149

not readily identifiable in packaging materials using infrared spectroscopy. Examples of these include, low-density polyethylene, linear low-density polyethylene, high-density polyethylene, and blends of these polymers. The blend ratios of these polyolefins can be estimated after calibration using the pure polymers.

The construction of the packaging material is then determined by comparing the data obtained from all the analytical techniques. Any layers that are difficult to identify are then identified by either detailed analysis on the isolated layer using FTIR and other analytical techniques, or by applying additional analytical techniques to the whole structure. For example, pyrolysis gas chromatography–mass spectrometry (GC–MS) can confirm the presence of a styrene/acrylate copolymer adhesive or vinylidene chloride/acrylate copolymer coating. The pyrolysis causes depolymerization, often to the starting monomers, which are then identified from their mass spectra. The technique can be applied to the whole construction. This is useful when FTIR analysis is not conclusive, or where the layer cannot be isolated for FTIR analysis. In the absence of a pyrolyser instrument, it is possible to perform the technique by briefly heating the sample in an inert atmosphere in a sealed headspace vial over a gentle Bunsen burner flame. Static headspace GC–MS analysis of the pyrolysate is then carried out. Hot stage microscopy is a particular useful technique for identifying layers. A key advantage of the technique is the ability to identify layers that cannot be isolated for analysis. In this technique, the packaging material cross-section is heated at a controlled rate under the microscope. The melting ranges of the individual layers can be observed and compared with the melting ranges observed by DSC. It should be noted that there is a difference of a few degrees centigrade in the melting ranges observed by DSC and hot stage microscopy:

The strategy for identification of a packaging material construction is summarize:

1. Examine a cross-section by optical microscopy; determine the number of layers and their thickness, tentatively identify the polymers in the layers.
2. Obtain a DSC of the whole material. This will identify all the crystalline polymers present in the structure.
3. Obtain infrared spectra from the surfaces. This will confirm the composition of the outer layers. Isolate fractions of the construction and obtain their infrared spectra to confirm the identifications made by DSC and optical microscopy.

Optical microscopy techniques can also be applied to packaging failure problems. Sections can be taken through a heat seal region to establish the integrity of the seal. Molecular orientation, melt flow, blend homogeneity, and crystallinity can be observed that can reveal the cause of stress cracking and other types of packaging failures.

## Analysis of Substances Related to Food Safety

It is sometimes necessary for technological reasons to use chemicals that have toxic properties in the manufacture of a food packaging materials. Also, there is the possibility that some of the chemicals and components used for food packaging materials can contain trace levels of toxic contaminants. Where toxic substances are unavoidably present in a food packaging material for any of these reasons, it is necessary to ensure that levels of these substances are restricted so that any transfer to packaged food does not exceed safety limits. The national regulations of individual countries control the safety of food packaging with respect to the substances with known toxic properties. In some countries the specific restrictions are contained in official recommendations or codes of practice. The primary restrictions are on the levels that migrate or transfer to the packaged food and are designated ‘specific migration limits’. However, in some cases the restriction is a permitted level in the packaging material, while for others the restriction is a limit on the quantity, which can be extracted. As might be expected where the safety of food is concerned, the set limits are often low requiring sensitive analytical methods.

### Food Contact Plastics

Vinyl chloride monomer used for the manufacture of PVC plastics intended for contact with foods provides an example where there is a low ‘specific migration limit’, plus a low limit on the level allowed to be present in the packaging material. These limits are contained in an EC Directive 78/142/EEC on PVC plastics and are: 0.01 milligrams per kilogram of food (10 ppb), and 1 milligram per kilogram of polyvinyl chloride.

Vinyl chloride is a gas at ambient temperature and the official EC analytical methods for both determinations use headspace GC with a flame ionization detector (FID). Where a determination exceeds the legislation limit, confirmation is required with headspace GC using either a different chromatography column, or a different detector, or with the gas chromatograph coupled to a mass spectrometer.

For the determination of free vinyl chloride monomer in plastics, the test sample is dissolved or dispersed in *N,N*-dimethylacetamide in a sealed vial and then equilibrated at 60°C before sampling the headspace. When determining vinyl chloride monomer in foods or food simulants, *N,N*-dimethylacetamide is again used with the sample in a sealed vial, with equilibration at 60°C.

Other volatile plastics monomers with similar migration limits, such as acrylonitrile and butadiene, are also determined by the headspace GC technique. For the measurement of 'nonvolatile' monomers in plastic food packaging and in foods or food simulants due to migration, high-performance liquid chromatography (HPLC) and ion-exchange chromatography techniques can be employed. Food and food simulants may give rise to interference problems with the analysis. Sample clean-up procedures are widely used such as solid-phase extraction of interference from extracts or size exclusion chromatography to remove fats and oils. Selective detectors such as mass spectrometers are now widely used for both liquid and gas chromatography.

Figure 4 is an ion-exchange chromatogram of phthalic acids. Terephthalic acid and isophthalic acid are monomers of polyester plastics. Orthophthalic acid is the internal standard. There are migration limits for both terephthalic acid and isophthalic acid in EC regulations of 7.5 and 5.0 mg per kg of food. The other main classes of substances in the 'safety' category, which can be present in food packaging plastics and for which analytical measurements are required, are the plastics additives. These substances perform the functions of plasticizers, antioxidants, antistatics, slip agents, and stabilizers. Of these additives, the plasticizers have been most extensively studied and analytical methods developed for their determination in the plastics and in packaged foods. The techniques are usually based on GC either with an FID or with a mass spectrometer as the detector. Key advantages offered by a mass spectrometer are selectivity of response and the ability to add a deuterated internal standard to the sample to compensate for the incomplete and variable recovery of the analyte in the analysis.

Migration testing of plastics packaging prior to use for compliance with any legislation limits is usually carried out with food simulants rather than actual foods. First, the analytical task is more often simple and, second, testing with a food simulant or simulants for a class of foods covers use with all foods in that class. The food simulants are simple liquids that represent different classes of foods. For foods where the liquid phase is largely water, distilled water is used as the simulant. For acidic foods (typically pH

**Figure 4** Separation of terephthalic acid (TPA), isophthalic acid (IPA), and orthophthalic acid (OPA) by ion-exchange chromatography. (From Ashby *et al.*, 1992.)

4.5 or less) the simulant is an acetic acid aqueous solution, and for alcoholic beverages and other foods containing alcohol, the simulant is an ethanol aqueous solution with strengths more or less equal to the alcoholic concentration in the beverage or food.

Selecting a simulant for foods containing fats and oils has not been easy. In the USA, *n*-Heptane is specified as the fatty food simulant in the Food and Drug Administration (FDA) regulations, although it is now recognized to give migration levels of specific substances well in excess of those that occur with the foods even after applying a suitable reduction factor. In Europe, olive oil has been selected as the fatty

food simulant with alternatives of sunflower oil or a synthetic triglyceride, known as HB307, developed specifically for migration testing. Alternatives to olive oil were considered necessary as it was known that various analytical problems arise with olive oil. The food simulants required for regulatory migration testing in the EC Member States on plastics packaging intended for use with foods, are listed in EC Directives 97/48/EEC and 85/572/EEC. These are shown in **Table 4** together with the classes of foods and beverages that they represent. The 85/572/EEC Directive also contains a table that specifies the simulant or simulants to be used for individual categories foods and beverages, and the 97/48/EEC Directive gives the test conditions of time and temperature corresponding to the intended conditions of use. Fatty foods contain various amounts of oils and fats. For those that have high oil or fat content the extent of migration of substances from the plastics is often higher than for those with low oil or fat contents. Consequently, reduction factors are applied to migration values obtained with olive oil to allow for the various levels of oil and fat in particular foods.

It has been generally accepted that migration from packaging materials into dry foods will be low compared to moist, liquid, or fatty foods. Accordingly, more work has been completed in developing simulants for these foods than dry foods. At the present time the only regulatory or generally recognized simulant for dry foods is Tenax (poly(2,6-diphenyl-*p*-phenylene oxide)). Tenax has been adopted as a dry food simulant because it is a dry porous polymer with a large surface area that exhibits high-adsorption characteristics for a wide range of volatile organic compounds. Tenax is therefore considered to be a worst-case dry food simulant for a wide range of dry foods. Other food simulants have been investigated for use with paperboard. A semisolid food simulant consisting of a mixture of diatomaceous earth, water, and olive oil has been used, as well as filter paper impregnated with olive oil.

**Table 4** EC food simulants for migration tests and the corresponding classes of foods

<i>Food simulant</i>	<i>Class of food or beverage</i>
Distilled water	Aqueous foods and beverages
3% (w/v) aqueous solution of acetic acid	Foods and beverages with pH 4.5 or less
10% (v/v) aqueous solution of ethanol <sup>a</sup>	Foods and beverages with 15% or less alcohol
Olive oil or sunflower oil or HB307	Foods containing fats and oils

<sup>a</sup> For a food or beverage with an alcohol content greater than 10% (v/v), a simulant with a similar ethanol concentration is used.

In addition to the requirement to measure the levels of individual specific substances that have migrated from plastic food packaging into foods or food simulants and have toxic properties, there is sometimes also the necessity to measure the total quantity of substances that are likely to transfer from the plastics to the food. This is called overall migration or global migration. The tests are carried out with food simulants as they are impracticable with foods. No attempt is made to identify the nature of the substances that have migrated from the plastic material. In the current EC 'food contact' plastics regulations there is an overall migration limit of 60 mg of substances from the plastics material per kilogram of food simulant ( $60 \text{ mg kg}^{-1}$ ), or expressed alternatively as 10 mg of plastic substances from  $1 \text{ dm}^2$  surface area of plastics test specimen ( $10 \text{ mg dm}^{-2}$ ). With the three aqueous based food simulants – distilled water, acetic acid, and ethanol solutions – the overall migration is measured by determining gravimetrically the nonvolatile residue in the simulant following exposure to the plastic test specimen. The values normally obtained with these aqueous-based food simulants are usually well below the regulation limit and in the region of 6–18  $\text{mg kg}^{-1}$  ( $1\text{--}3 \text{ mg dm}^{-2}$ ). As the tests are most often carried out on test specimens with a surface area of  $1\text{--}3 \text{ mg dm}^{-2}$  the total quantities of migrating substances are typically a few milligrams. Consequently, care has to be taken with the gravimetric measurement to ensure reliable results are obtained. After evaporating the simulant to dryness the nonvolatile residue is dried in an oven at  $110^\circ\text{C}$  until constant weight is obtained. It has been found, however, that particular care has to be taken when using glass evaporating dishes to ensure that there is adequate time allowed for both the heating period in the oven and the cooling period in the desiccator for the mass to stabilize before each weighing. With metal evaporating dishes the mass of the dish and residue stabilize more quickly, but with the acetic acid simulant it is necessary to use dishes made of platinum, or a metal with similar chemical resistance, to prevent additional errors from corrosion products.

To measure overall migration with olive oil or alternative simulants, the method used with the aqueous-based food simulants is obviously not applicable. With oil-type simulants the test is carried out by measuring the loss in mass of the test specimen after exposure to the food simulant. However, most plastics absorb some of the oil that then has to be extracted and quantitatively measured before the true loss in mass can be calculated. The extraction solvent that has been most commonly used in the past is

1,1,2-trichlorotrifluoroethane, as it is a good solvent for olive oil but does not dissolve most plastics. As this solvent is a chlorofluorocarbon its main use and supply is being phased out and pentane and diethyl ether are now used instead for the extractions.

Once the extraction has been completed the olive oil is quantitatively analyzed by hydrolyzing to the fatty acids, methylating to form the methyl esters, and measurement by GC. The value obtained is subtracted from the mass of the test specimen after exposure to the olive oil, to allow the overall migration value to be calculated. The test method has a reputation of poor precision and reliability not only due to the complex procedure, described above, but also due various other factors that are known to influence results, such as moisture absorption by the plastic test specimens, incomplete extraction of the olive oil, and change in composition of the extracted olive oil. The overall and specific migration analytical test methods have been established as Standards by the European Committee for Standardisation (CEN). Reference plastics are also available with certified migration values in olive oil (Institute for Reference Materials and Measurements BCR, Geel, Belgium, sales@irmm.jrc.be).

### **Paper and Board**

Most paper and board food packaging materials are not used in direct contact with liquid foods and consequently migration tests with liquid food simulants are not considered appropriate. Paper and board packaging does, however, come into direct contact with various moist and fatty foods where migration of substances into the food can sometimes occur. No simulants have yet been selected to specifically represent these classes of foods in migration tests on paper and board. To ensure that the paper and board material is suitable and safe to package foods, extraction tests are often carried out. The extraction test is performed with cold or hot water, or sometimes with dilute acids and solvents and is considered to be a more severe test than a migration test. Analytical measurements are then carried out for specific substances on the extraction liquid. For example, tests are carried out for free formaldehyde, which can arise from wet-strength additives of the melamine formaldehyde or urea formaldehyde types. A typical analytical method for the determination of free formaldehyde in the extracts is based on colorimetric procedures using chromotropic acid or acetylacetone (pentane-2,4-dione). With paper and board products there is concern that there could be toxic contaminants present that in turn could transfer to the food when used as packaging. These

possible contaminants include: the toxic heavy elements arsenic, mercury, lead, cadmium, and chromium, plus chlorophenols and polychlorinated biphenyls (PCBs). With extraction liquids such as water or dilute aqueous acid solutions, the toxic heavy elements can be analytically determined using atomic absorption spectroscopy. Arsenic can be measured with the hydride generation technique, mercury with the cold vapor technique, and the other metals by the standard flame technique. Inductively coupled plasma atomic emission spectroscopy is now also widely used. Pentachlorophenol and other chlorophenols can be determined by either GC or HPLC. When using GC the chlorophenols are best derivatized to form the methyl or acetyl derivatives in order to improve the chromatographic performance and the analytical precision. These analytical techniques have also been used in the detection and analysis of chlorophenols suspected of being responsible for odors and food tainting, as described later. The PCBs are determined in extracts from paper and board materials by GC with an electron capture detector or mass spectrometer.

Two compounds are currently of particular interest in paper and board. Diisopropyl naphthalene (DIPN) is a mixture of isomers that until recently were widely used in carbonless copy papers as ink solvents. Although it is currently being replaced it occurs as a persistent contaminant in recycled paper and board. Various studies have shown that it is able to migrate from paperboard into food. There is a draft CEN analytical method available. This method involves acetone extraction and quantification by GC-MS using diethyl naphthalene as an internal standard. There is currently no limit for DIPN but levels are being monitored to reduce concentrations in recycled paperboard.

Two related compounds are 3-monochloropropane-1,2-diol (3-MCPD) and dichloropropanol. These arise in paper board due to the hydrolysis of epichlorohydrin-based wet strength agents. 3-MCPD can occur in food from hydrolyzed vegetable protein. The limit in food is 120 ppb. In packaging the specific migration limit is 12 ppb in the food. The dichloropropanol does not at present have a limit. However, the German BGVV recommendations (widely accepted as useful guidelines) list a limit of 2 ppb in a hot water extract. A convenient method of analysis is to extract the two compounds with water. The water extract is then totally absorbed onto a diatomaceous earth cartridge. The cartridge is then washed with a large volume of diethyl ether. The water is retained on the cartridge and the 3-MCPD and dichloropropanol extracted and eluted by the diethyl ether. The ether is then concentrated by

evaporation and the two compounds derivatized and injected for analysis by GC-MS.

### Metal Packaging

Cans are widely used to pack food. In some cases tinplated steel cans are used, for example, for packing fruit. Predominantly, the cans are internally coated with a polymeric coating to prevent corrosion or food spoilage. A considerable amount of work has been done in recent years investigating the extent to which compounds present in the lacquers migrate into food.

Attention has focused on the chemical compounds bisphenol A, BADGE, and BFDGE. Bisphenol A is manufactured from the reaction of phenol with acetone. The bisphenol A is further reacted with epichlorohydrin to produce bisphenol A diglycidyl ether (BADGE). BADGE is then polymerized and cross-linked in a stoving process to produce an epoxy phenolic coating that has high chemical and mechanical resistance. These coating are called bisphenol A-epoxies.

Alternatively, phenol may be reacted with formaldehyde to generate bisphenol F. Unlike bisphenol A, bisphenol F is a mixture of isomers rather than a discrete compound. Bisphenol F can be subjected to a condensation process in which a polymeric resin called Novolac is produced. The Novolac can be reacted with epichlorohydrin to produce a polyglycidyl ether and these are called novolac glycidyl ethers (NOGE). NOGE is not used to produce epoxyphenolic coatings, as is the case with BADGE.

Organosol coatings are dispersions of PVC in softener, solvent, and other resins. Solid contents are typically 40–80%. The coating is stoved to evaporate off the solvents and cure the resin. BADGE is often added as an additive to scavenge for hydrochloric acid generated from the PVC during curing. Alternatively, NOGE is used as an additive instead of BADGE.

The most widely used lacquer types for food cans, where the food is retorted in the can to ensure preservation are:

- epoxyphenolic and
- organosol

Epoxyphenolic lacquers are universally used for both can bodies and ends for two- and three-piece constructions, although more usually for shallow draw cans. Beverage can bodies are commonly epoxyamino coated, and the 'easy-open' end and deeper draw two-piece cans are organosol coated. Coatings may contain residual BFDGE and bisphenol F arising from the NOGE in organosol coatings and bisphenol

A as well as BADGE arising from the use of BADGE in organosol and epoxy phenolic coatings. Possible residues remaining in the coatings are listed below, all of which have been found to contaminate the food:

- BFDGE
- BADGE
- Bisphenol A
- Bisphenol F

BADGE and BFDGE undergo hydrolysis and addition of hydrogen chloride released from the PVC organosol in aqueous foods and a series of reaction products result. Concern has been raised over these reaction products. These are listed below:

- BADGE · HCl
- BADGE · 2HCl
- BADGE · H<sub>2</sub>O · HCl
- BADGE · H<sub>2</sub>O

These decomposition products result from the ring opening on the epoxy group of which there are two. The legislation (Directive 2002/16/EC, February 20, 2002, on epoxy food contact materials) specifies a migration limit of 1 ppm in the food. This limit is the total of all the reaction products and BADGE added to the BFDGE and its reaction products. In addition, there is a requirement of no detectable migration of NOGE at a detection limit of 0.2 mg kg<sup>-1</sup> in the food or 0.2 mg/6 dm<sup>2</sup> in the can. The decomposition product BADGE · 2H<sub>2</sub>O in food is ignored as this is not of toxicological significance. However, it must be included if the migration test is done on food simulants as there is the risk of forcing decomposition through to the BADGE · 2H<sub>2</sub>O and underestimating the other compounds. The legislation is due for review in 2004 as the toxicity of the chlorohydrins is not at present established.

### Analysis of Substances Causing Taint

Taint from food packaging is very rare when one considers the tonnage of packaged food consumed each year. Tainting chemical compounds present or derived from the food packaging are often volatile compounds. With plastics these odorous volatiles can be: monomer residues, reaction by-products from the polymerization process, breakdown products of certain additives and contaminants. For example, with polystyrene plastics high levels of styrene monomer produce a very characteristic odor and a number of incidents of tainting from styrene monomer have been reported. With polyethylene terephthalate (PET) plastics, acetaldehyde can be formed during

the polymerization process and when PET is used for beverage bottles the acetaldehyde can cause tainting of the beverage. With paper and board materials the volatiles arise mainly from natural lipids and resins originating from the wood raw material, but some can come from synthetic resins used in surface coatings that are applied for improved printability and appearance. The predominant volatiles originating from the wood lipids and resins are usually aldehydes, carboxylic acids, and alcohols. The odors of some of these aldehydes are not unpleasant being described as 'grassy', but others have 'rancid' odors. Many of the carboxylic acids and alcohols have strong sharp odors. The synthetic resin binder used in the surface coatings is typically a styrene/butadiene copolymer that can contain odorous reaction by-products such as 4-phenyl cyclohexene. If solvent-based adhesives are used in sealing the packaging or to bind layers together, and if the finished packaging is printed with solvent-based inks, solvent residues can add to the list of volatile substances. If the more odorous of these print solvents and volatile substances are present in sufficient quantities they can cause the packaging to be odorous and in turn result in tainted foods.

Two classes of highly odorous substances that have been known to contaminate food packaging and result in food tainting are the halophenols and the related haloanisoles (methylated chlorophenols and bromophenols). In the past contamination was invariably with the chlorophenols and corresponding anisoles from wooden pallets and surfaces treated with wood preservers or phenol-based disinfectants. The anisoles are generated by microorganisms such as molds from the phenols. Recently, there has been a noticeable trend toward increased contamination with the bromophenol and corresponding anisoles. This reflects the substitution of bromophenols for chlorophenols in wood treatments. The odor threshold for tribromoanisole in water is  $8 \text{ pg l}^{-1}$  ( $8 \times 10^{-12} \text{ g l}^{-1}$  or 8 parts per trillion, ppt). Low-detection limits are therefore required for such taint investigations. Concentrations above 1 ppb in the packaging are often sufficient for tainting to occur. Polyethylene is the most widely used polymer in contact with food, usually in the form of a thin inner layer of a food pack. It therefore only requires contamination of a few sacks of polyethylene granules with the anisole to result in tainting of a large amount of food.

Analytical measurements and investigations are therefore carried out to detect and measure volatile odorous substances in food packaging either for quality control purposes or when odor and taint problems arise. The technique of choice is GC-MS.

For odor investigation the chromatograph is fitted with an odor port so that the flow from the analytical capillary column is split via a T piece to an odor port. By this means it is possible to smell compounds eluting from the capillary column simultaneously with their detection by the mass spectrometer. This enables an odorous compound to be identified and quantified in food and packaging.

Isolation and concentration of tainting compounds from the rejected food and packaging prior to analysis is usually the most challenging step in the investigation. Dynamic headspace sampling is widely used. In this technique, a sample of the packaging material is placed in a vessel that is closed, heated to a temperature of  $\sim 70^\circ\text{C}$ , and then purged with an inert gas such as nitrogen or helium. Volatiles released from the packaging are removed by the purge gas, trapped, and concentrated on a porous polymer such as Tenax. Transfer of the volatiles from the porous polymer to the gas chromatograph is performed by thermal desorption or by solvent elution and injection as a solvent solution. The chromatogram in Figure 5 shows volatile substances that have been collected by the dynamic headspace technique from a printed carton-board that had caused tainting in a packaged cake. The tainting was attributed to the benzophenone that appears as the large peak at just below 16 min. Benzophenone is used as an initiator in ultraviolet radiation cured printing inks. The peak at 3.1 min is the aldehyde, hexanal, which originated from the pulp used to make the board. The cluster of peaks from  $\sim 5.5$  to  $\sim 7$  min is volatiles from the synthetic resin binder in the board coating. None of these substances produced detectable odors.

The Likens-Nickerson extraction technique can also be used as a concentration technique, particularly for those volatile substances that are steam volatile such as the chlorophenols and chloroanisoles, and also when carrying out an analysis for the packaging volatiles in foods. The sample is boiled in a flask with water. Consideration must be given to the pH of the sample in the water. Basic compounds will be present as water-soluble involatile salts in boiling water at low pH, and acids as the corresponding salts in boiling water at high pH. The procedure is therefore best carried out under basic conditions and then repeated after acidification with a few drops of nitric acid. The steam is condensed and continuously extracted with a suitable nonwater-miscible solvent, any solvent-soluble volatile substances being transferred to the solvent. After concentration of the solvent solution by evaporation of the solvent with a Kuderna-Danish apparatus, the analysis is again performed using a gas chromatograph coupled to a mass spectrometer.

**Figure 5** Chromatogram of volatile substances from a carton-board food packaging printed with a UV-cured ink. Benzophenone, the printing ink component responsible for tainting of packaged food, is represented by the peak at 15.7 min.

Solid-phase micro extraction is a useful technique in which volatiles are partitioned from the sample onto fibers coated with polar or nonpolar bonded phases. The fiber is then placed directly into the heated injection port of the GC where compounds are volatilized and carried onto the capillary column. The technique is less sensitive than the techniques described above as it is an equilibrium process. However, modern ion trap mass spectrometers have increased in sensitivity and the technique is becoming widely used.

### Residual Solvents

Solvent residues from printing and adhesives have the potential to cause food tainting. Typical solvents used in printing with characteristic, easily detectable odors are aliphatic esters, such as ethyl acetate, isopropyl acetate, and *n*-propyl acetate, the alcohols isopropyl alcohol and *n*-propyl alcohol and hydrocarbon mixtures, particularly aromatics. Regular tests are carried out by printers of food packaging to ensure that the concentrations of solvent residues are maintained below the odor and tainting threshold levels. The most widely used analytical technique to measure the levels of solvent residues is GC headspace analysis. Portions of the packaging are placed in sealed vials or other suitable containers and heated

at a set temperature for a prescribed period of time. The headspace is then sampled by means of a gas syringe or automatic sampling unit and injected into a suitable gas chromatograph with an FID. As the measurements are often carried out for quality control purposes, short heating times are sometimes used with external calibration and the measurements do not always accurately determine the solvent residues in the packaging, but do give reproducible results. This is the case with UK, BSI Standard BS6455 – Monitoring the levels of residual solvents in flexible packaging materials – and also the corresponding American ASTM Standard F 151-86. There are two draft EN standard methods in existence, prEN 13628-1 (absolute method) and prEN 13628-2 (industrial quality control monitoring method).

## Introduction

Forensic sciences group the scientific principles and technical methods applied to the investigation of crimes, litigations in civil matters, or regulatory and state administrative matters. Results are presented as

scientific expert evidence in the courts of law. The essence of forensic science is the study of traces, which, as a result, become information in the form of physical evidence or intelligence to lead investigation. The scientist assists the magistrates in determining the existence of a break in a rule (mostly crime), associate the evidence to a source (hopefully the author) or to a type of activity (determining that the action is the cause of the observed result). The traditional use of forensic science evidence is the identification of the author of a crime, but in recent years the value of physical evidence has taken a new dimension because of its value in reconstructing events (forensic intelligence) or because of its physical nature, it has become the only type of evidence that can be tested again to demonstrate wrongful convictions.

Physical evidence presents essential and unique features that make it so useful. It exists! This means that it can be tested repeatedly if necessary, as long as it is available, unlike statements (of witnesses, victims, or suspects which vary notoriously over time, or which may even be lies). The fact that it is physical evidence also means that there is no need for personal data for it to be useful. This allows extensive possibilities for data exchange without infringing personal data protection regulations. A trace in case A may be linked to a trace in case B across administrative borders. If the source of the trace of case A is known, then the source for the trace in case B may be known. With this information, investigation authorities may require international cooperation through the usual legal channel (bilateral agreement, Interpol, etc.). The study of physical evidence could be compared to the interrogation of a silent witness who never lies and protects human rights because it is not handling persons but only traces.

Locard in 1920 expressed the fundamental axiom, sometimes referred to the 'Locard exchange principle', that, in essence, every contact leaves a trace: any person committing a crime leaves something at the scene that was not there before and carries away traces that were not associated with him when he arrived. When an item is submitted to the laboratory for analysis, the usual questions are:

1. What is it? The answer to this question covers the physicochemical nature of the trace material.
2. Can it be associated with a source (usually a suspect) without any possible dispute? This relates to the specificity of the analyses or in terms usual in forensic science, to the identification or to the individualization of the source.
3. Is it the result of the action (the crime)? This question relates to the pertinence of the trace, whether the investigated action is its cause or the trace belongs to an unrelated action that happened before or after the investigation.
4. Is there another instance with the same type of trace, potentially from the same source, that demonstrates a potential link between two cases or more cases?
5. Finally, What are the risks that this identity might be accidental? That is, that another source may match the trace, other than the purportedly identified source. This relates to population studies used to find out the spread of specific attributes commonly analyzed and the risk of wrongful attribution to a specific source.

To answer these questions, there is a great need for all possible forms of chemical analyses to determine (1) the chemical make-up of a sample; (2) the frequency distribution of this type of material; (3) the permanence and stability of the trace; and (4) the variation in the composition over the population of materials of this type. The ultimate purpose is chemical identification, comparison, and, finally, interpretation of the results obtained in the context of the events.

One essential factor that differentiates this type of analyses from other analytical procedures is that the trace is the result of a past and uncertain action and its quantity cannot be modified. One can only assume that it is representative of the chemical make-up of the source and this assumption has to be taken into account when interpreting results. An essential limiting factor therefore comes from the sample that cannot be selected as in a true sampling procedure except when mass produced crime material is seized (illicit drugs, counterfeit).

The items may range from materials of natural origin (biological traces such as blood, hair, seminal stains, polymorphic enzymes, or drugs such as opiates, hallucinogens); materials of natural origin manufactured into a finished product (such as glass, paper, petroleum products), to completely synthesized and manufactured products (such as plastics, paints, fibers, drugs). Furthermore, large amounts may be available for analysis (e.g., in drug trafficking) or minute, submicrogram samples may be all that is available to the analyst (paint chip, arson residue, etc.). This requires precise and accurate analytical work on increasingly smaller amounts of material. Complex and modern methods of instrumental analysis therefore equip most modern forensic science laboratories. However, the methodology requires a stepwise progression from simple, general, rapid, widely applicable, and nondestructive screening methods, ranging from simple visual comparative examinations to the more discriminating and specific

methods, or combinations thereof, in order to reach the conclusion of identity.

For the results to be valid, it is essential that not only the items (crime or comparison samples) must be collected in a controlled, reproducible fashion, but also following an admissible legal procedure that varies from country to country (e.g., chain of evidence in common law; seals in other formal legal systems).

## General, Nondestructive Techniques

### Optical Examinations

The first methods are simple optical examinations with the unaided eyes (transmitted, reflected, or grazing light) under natural daylight and filtered or unfiltered artificial light. These observations may be extended from ultraviolet (UV) to infrared (IR) using light converters (attached to video cameras). Attributes such as color, shape, design, dimensions, and surface quality allow rapid selection and discrimination of a large majority of products encountered in the investigation. This may lead to exclusion (elimination of suspects) or information useful in criminal investigation (criminal intelligence) and is an essential part of operational forensic science.

Microscopy extends the capabilities of our eyes; the morphology of small objects is precisely delineated (in the micrometer range for optical microscope down to the picometer range for the electron microscope), the fine details of their physical structure are analyzed, physical characteristics are precisely measured (length, width, angles, thickness, quantity), and optical attributes analyzed (color, opacity, refraction index, reflectance, phase change, photoluminescence, birefringence, phase contrast, etc.). Furthermore, microcomparisons by juxtaposition or superposition are obtained with specialized comparison microscopes (Figures 1 and 2). Not the least advantage is that microscopy produces an enlarged image that can be recorded photographically to document, demonstrate, identify, and measure objects to help the court (judge, jury) understand and objectively visualize what the forensic scientist has discovered.

All evidence types showing complex morphological designs or patterns do not warrant further analyses: it is generally all that is needed to discriminate, eliminate, classify, and ultimately prove individual identity of broken glass (Figure 3), paint and paper by physical fit, as well as toolmarks, firearms, footmarks, handwriting, signatures, and fingerprints by comparison of complex accidental designs (although with the latter a chemical reaction is often needed to make the print visible).

**Figure 1** Comparison microscope with camera system. (Courtesy of Leica.)

**Figure 2** Identification of a firearm by comparison of the microstriations marked of the bullet. Left crime sample, right comparison sample.

**Figure 3** Conchoidal structure of glass fracture. Face view of the two sides of fractured glass shown side by side. The physical fit proves the singular identity of source.

### Spectroscopic Techniques

Depending on the interaction of electromagnetic energy with the matter constituting the evidential items, techniques that give simple spectra (such as with UV absorption spectrometry) permit discrimination only on the class level, i.e., showing the presence or absence of certain chromophores within the sample analyzed. Methods that result in complex spectra are much more selective, to the extent that they may individualize a chemical product. The morphologic complexity of the spectra is often abusively referred to as chemical 'fingerprinting', reflecting the uniqueness of a given product (e.g., the 'fingerprint' region of the IR spectrum between 500 and 2000 wave numbers (6–10  $\mu\text{m}$ )).

Three main types of nondestructive spectroscopic techniques are commonly used: absorption, emission, and physical techniques based on the modification of rays of electromagnetic energy (refraction, scattering, polarization, and refraction).

UV and visible absorption (also reflectance) microspectrometry has an extensive use in screening pigments and colors in paints, inks, and fibers, whereas it has found applications mostly for quantitative measurements in drug analysis (in particular for barbiturates). The development of sensitive IR spectrometers with Fourier transformation and

microspectrometers has meant rapid generalization of the technique for the analysis of organic materials from fibers, paint, glue, polymers, drugs, greases, and oils to inks, papers, and toners. Many IR databases have been produced that are extensively used in forensic analyses. One such database is the car paint database, now in use extensively throughout the world. Such databases allow exchanges because they concern material information rather than personal information covered by national personal data protection regulations.

Emission spectroscopic methods, due to their high intrinsic sensitivities, are techniques of choice much sought after in forensic science. Fluorimetry has been applied to the analysis of mineral oils, grease, inks, and drugs (e.g., LSD), whereas X-ray fluorescence has found extensive applications in the analysis of inorganic materials (e.g., paint pigments and glass).

Raman spectroscopy has shown great potential in forensic science because it is nondestructive, it has a high selectivity, and the analyses are fast. Methods to minimize interference and enhance the Raman signal caused this renewed interest.

The determination of refractive indices of glass is routinely performed and allows extensive discrimination and valuable evidence in cases of break-ins, aggressions, and hit-and-run accidents. The determination is obtained by immersion of the sample in an oil whose refractive index is calibrated on a hot plate under a microscope. The disappearance of the delineaation line (Becke's line) around the glass sample gives the temperature at which the glass and oil have the same refractive index.

The comparison of fibers and soil particles (and other anisotropic crystals) between two crossed polarizing filters under a microscope is a powerful and discriminating tool. The birefringence measurement gives important qualitative information on the products analyzed.

Scanning electron microscopy with energy dispersive X-ray spectrometry has found extensive applications in the analysis of glass, paint, fibers, and especially in the identification of gunshot residues (where it is the method of choice). This technique offers high resolution, great depth of field, and qualitative and quantitative information on small samples. However, although this technique has much to offer, its use in crime detection is often overrated.

In the late 1960s and the 1970s, neutron activation analysis has received much attention in forensic science because of its ultimate sensitivity combined with specificity. The early optimism has been dampened by the difficulty in interpreting results due to the variation of trace elements within samples at a given time and over a length of time. It has been used mainly in

glass, gunshot primer residue (determination of Pb, Ba, and Sb), and toxicological (As, Th) analyses.

## Destructive Techniques

All techniques based on a chemical reaction or which separate the components of a mixture, even if the reaction is reversible or the separation does not chemically modify the components of the mixture, are considered destructive in forensic science because the integrity of the sample in its original form is often paramount in the criminal trial (it offers the warranty that the analyses can be tested and reproduced by an independent analyst).

## Spectroscopic Techniques

Atomic absorption spectroscopy has been at the forefront of inorganic analyses in forensic sciences from the late 1960s. With the development of non-flame atomizers (carbon furnace) and high-intensity lamps (electrodeless discharge, hollow cathode), many elements of interest, due to their high toxicity, are currently routinely analyzed (As, Th, Sb, Cd, etc.). It has found applications in hair, fingernail, paint, fuels, lubricants, fibers, polymers, papers, pharmaceutical, gunshot residue, forged and counterfeited coins analyses. However, because of the high sensitivity and the need for sample preparation, background noise and high impurity levels hamper a more routine use of this technique.

Laser and inductively coupled plasma (ICP) emission spectroscopy constitute powerful multielement qualitative and quantitative tools for the analysis of metals, paints, and glass. Finally, ICP with mass spectrometry (MS) makes an increasing impact on the analyses of trace evidence from pollution source determination to traditional trace exploitation.

MS is accepted as an indispensable technique in the analysis of drugs and their fate in the body. Lately, there has been an increase in the frequency of xenobiotic studies that have taken advantage of tandem MS to screen complex biological samples for the presence of drug-related products. But mostly MS is used in combination with a separation technique (e.g., chromatography) in forensic science.

## Chemical Reactions

The need for rapid results, often in the field, in order to detect dangerous products (e.g., explosives) and/or products subject to trafficking (e.g., drugs), has led to the development of many chemical screening tests that are commonly used by police technicians. This involves mostly color or crystal tests that require confirmation by laboratory analyses.

Other color reactions employed in forensic science are simply used to create a contrast and make structural entities visible for taxonomical or identification purposes, especially in connection with microscopical examination (e.g., coloration of sperm heads with Baecchi's stain – acid fuchsin S and methyl blue).

Immunological methods have become the standard screening methods in forensic toxicology laboratories and have provided sensitive qualitative and quantitative means of testing blood and urine. Radioimmunoassay kits exist for the testing and measurement of opiates, amphetamines, cocaine, barbiturates, cannabinoids, benzodiazepines, etc. The introduction of monoclonal antibodies has allowed the development of increasingly specific tests. Various immunological techniques have been devised using enzyme mediated amplification to avoid the drawbacks of using radioactive materials (e.g., enzyme multiplied immunological technique and enzyme linked immunosorbant assay). All require analytical confirmation for legal purposes.

## Analytical Separations

Most products or contact traces found as evidence are made up of complex combinations of molecules and atoms that constitute our environment. This complexity makes that the world is infinitely variable and each item is unique in its make-up and design. This is exploited to individualize, categorize, or exclude the identity of samples from contacts or any other event connected with a crime. This process necessitates the extraction and separation of often minor components of material and requires careful and optimal separation techniques. From simple sample preparation (such as liquid–liquid extraction) in toxicological analyses, the forensic scientist may use the whole range of separation techniques from thin layer chromatography (inks, fiber dyes, drugs, etc.), gas chromatography (GC) (arson accelerants, drugs, solvents, ethanol, etc.), and high-performance liquid chromatography (drugs, paints, inks, oils, etc.) to capillary electrophoresis (inks, proteins, enzymes, DNA fragments), isoelectric focusing (blood products, serology, proteins), isotachopheresis, etc. The separation may be based on differences in solubility, size, polarity, volatility, electric charge, etc. Field tools based on separation methodology have been developed and are now in common use at scenes of crime or for security checks (airports, public administrations, military, police, or custom offices, etc.) to detect materials such as illicit drugs and explosives.

All separation techniques are used in combination with other analytical methods designed to make products visible (on a thin-layer chromatogram, for

example) or to give an electrical signal at the end of a capillary in GC (e.g., flame ionization detection). With spectrometric detection, an additional identification capability (such as GC–MS or high-performance liquid chromatography (HPLC)–UV/visible diode array detection, etc) increases the information content of the analysis. This allows often powerful discrimination that may require interpretation.

Developments in the analysis of genetic material (DNA profiling) consist of first isolating genetic material (DNA) by extraction followed by enzymatic digestion with restriction enzymes of specific polymorphic sections of the DNA molecule. These fragments are then multiplied by splitting the two DNA strands and synthesizing their complementary strands with a natural polymerase using thermal cycles. After a determined number of cycles, the multiplied DNA fragments are separated and detected by employing an electrophoretic method. In that manner, complex biochemical mechanisms are used to produce an extremely selective and sensitive analytical result to be presented before the Court of Justice.

## Interpretation

In order to distinguish between samples of different origin that contain fairly similar amounts of the same compounds, accurate and precise quantitative measurements of very low concentrations (in the ppb range) are often necessary. Statistical analysis can therefore represent a challenging problem usually mastered by most analysts.

When samples are not discriminated, the problem of the interpretation of evidence becomes primordial and much more difficult. There is some need to know the risk or the probability that two items come from different sources, but are not discriminated. This is expressed by the discrimination power of the attribute analyzed that defines the effectiveness of that attribute to differentiate samples in forensic science. Extensive databases are used to compute the probability that two randomly selected samples will be discriminated when the attribute is analyzed or measured. This probability is, in effect, the discrimination power that has been calculated for uncorrelated, correlated, and continuous variables such as blood grouping systems, drugs, glass, paints, etc.

This probability is useful; however, it only gives an indication to the forensic scientist as to his ability to distinguish between closely related, but different, materials. It does not give an indication of the value of the evidence in a given situation, i.e., the probability of finding this type of evidence material on a person connected or inversely, unconnected with a

crime. Therefore, other data such as the preeminence or rarity of given materials, their retention capacity on the victim or assailant in a crime situation, and their variation over a population of interest are necessary. These data are collected to estimate the risk of finding a particular type of evidence on an innocent person as compared to the chance of finding it on the guilty party. It all comes down to the smaller the coincidence probability, the greater the evidential value of a match. This is the object of intensive and extensive research in a number of laboratories around the world, and it is here that real progress can be expected in the near future, rather than in the development of new analytical techniques. The treatment of the data is the object of Bayesian statistics that are now being applied to intelligent knowledge-based systems to interpret the value of evidence under a given set of circumstances.

In forensic intelligence and crime analysis, data may be treated differently. It is less essential to avoid false incrimination. The essence in investigation is to have reliable information that shows potential links between crimes or events over time and space. Extracting cases from complex files overloaded with fuzzy information and showing potential links allows the review of these cases seen as a group (important in serial crimes). The demonstration of links creates a picture that becomes clearer with each new data of what can be described as a crime series whose profile can determine regularities in the activities of the criminal or criminal group. This has developed into a very profitable and proactive methodology to fight against serial crimes. Forensic science offers solid and reliable evidence that helps remove linkage blindness unlike many attempts at profiling that increase fuzziness by combining complex information whose reliability is often unknown. Forensic intelligence is making strong advances and is credited with promising successes.

### Introduction

Alcohol commonly refers to ethanol that is found in beverages made since ancient times. Alcoholic beverages are consumed worldwide except in some countries where drinking is prohibited for religious and cultural reasons. The excessive consumption of alcoholic beverages has a significant impact on society, and ethanol is the leading toxic substance handled in clinical and forensic toxicology. Traffic accidents associated with alcohol consumption are a serious social problem, and more than 1 million driver's licenses per year have been revoked worldwide because of inebriation. Annual fatalities associated with alcohol consumption occur in more than 15 000 people in the European Union and 10 000 people in the USA. In Japan, 8000–9000 people have been involved in fatal traffic accidents annually and ~15% of them were victims of drunken driving. Legal alcohol limits for driving are different among countries. In the USA, 49 states (all except Massachusetts) have laws defining it as a crime to drive with a blood alcohol concentration at or above  $0.8 \text{ mg ml}^{-1}$  in 34 states and  $1.0 \text{ mg ml}^{-1}$  in 15 states. In other countries, the legal limits are in the range  $0.2$ – $0.8 \text{ mg ml}^{-1}$  or mg per g. In Sweden and Japan, drunken driving is more strictly defined as blood alcohol concentrations of  $0.2 \text{ mg per g}$  or more and  $0.3 \text{ mg ml}^{-1}$  or more, respectively.

Widmark reported the first analytical method for measuring ethanol in body fluids in 1922. This method was based on the oxidation of ethanol with potassium dichromate followed by titrimetric analysis.

Later, an enzymatic method based on oxidation of ethanol by alcohol dehydrogenase (ADH) and nicotinamide adenine dinucleotide (NAD) followed by spectrophotometric analysis was reported. Current methods for detecting ethanol in body fluids are predominantly based on physicochemical techniques. A gas–liquid chromatographic (GLC) method is the most widespread because it is easy, rapid, and has high specificity and accuracy. Analytical methods used to determine alcohol in body fluids are summarized in Table 1.

### Sample Collection and Handling

#### Living Persons

Blood is usually collected from the cubital vein using evacuated glass tubes (5 or 10 ml vacutainer tubes)

**Table 1** Analytical methods used to determine alcohol in body fluids

Analytical method	Principle of detection
Chemical oxidation	Reduction of potassium dichromate (yellow–orange) to chromium(III) ion (green) in the presence of alcohol and sulfuric acid
Enzymatic oxidation	Reduction of nicotinamide adenine dinucleotide ( $\text{NAD}^+$ ) to NADH (UV absorbed at 340 nm) in the process of alcohol oxidation catalyzed by alcohol dehydrogenase (ADH)
Gas chromatography (direct injection)	Injection of a liquid sample mixed with an internal standard and detection with flame ionization detector
Gas chromatography (headspace injection)	Injection of headspace vapor after incubation of a closed vial containing a liquid sample mixed with an internal standard and detection with flame ionization detector

### Introduction

Alcohol commonly refers to ethanol that is found in beverages made since ancient times. Alcoholic beverages are consumed worldwide except in some countries where drinking is prohibited for religious and cultural reasons. The excessive consumption of alcoholic beverages has a significant impact on society, and ethanol is the leading toxic substance handled in clinical and forensic toxicology. Traffic accidents associated with alcohol consumption are a serious social problem, and more than 1 million driver's licenses per year have been revoked worldwide because of inebriation. Annual fatalities associated with alcohol consumption occur in more than 15 000 people in the European Union and 10 000 people in the USA. In Japan, 8000–9000 people have been involved in fatal traffic accidents annually and ~15% of them were victims of drunken driving. Legal alcohol limits for driving are different among countries. In the USA, 49 states (all except Massachusetts) have laws defining it as a crime to drive with a blood alcohol concentration at or above  $0.8 \text{ mg ml}^{-1}$  in 34 states and  $1.0 \text{ mg ml}^{-1}$  in 15 states. In other countries, the legal limits are in the range  $0.2$ – $0.8 \text{ mg ml}^{-1}$  or mg per g. In Sweden and Japan, drunken driving is more strictly defined as blood alcohol concentrations of  $0.2 \text{ mg per g}$  or more and  $0.3 \text{ mg ml}^{-1}$  or more, respectively.

Widmark reported the first analytical method for measuring ethanol in body fluids in 1922. This method was based on the oxidation of ethanol with potassium dichromate followed by titrimetric analysis.

Later, an enzymatic method based on oxidation of ethanol by alcohol dehydrogenase (ADH) and nicotinamide adenine dinucleotide (NAD) followed by spectrophotometric analysis was reported. Current methods for detecting ethanol in body fluids are predominantly based on physicochemical techniques. A gas–liquid chromatographic (GLC) method is the most widespread because it is easy, rapid, and has high specificity and accuracy. Analytical methods used to determine alcohol in body fluids are summarized in Table 1.

### Sample Collection and Handling

#### Living Persons

Blood is usually collected from the cubital vein using evacuated glass tubes (5 or 10 ml vacutainer tubes)

**Table 1** Analytical methods used to determine alcohol in body fluids

Analytical method	Principle of detection
Chemical oxidation	Reduction of potassium dichromate (yellow–orange) to chromium(III) ion (green) in the presence of alcohol and sulfuric acid
Enzymatic oxidation	Reduction of nicotinamide adenine dinucleotide ( $\text{NAD}^+$ ) to NADH (UV absorbed at 340 nm) in the process of alcohol oxidation catalyzed by alcohol dehydrogenase (ADH)
Gas chromatography (direct injection)	Injection of a liquid sample mixed with an internal standard and detection with flame ionization detector
Gas chromatography (headspace injection)	Injection of headspace vapor after incubation of a closed vial containing a liquid sample mixed with an internal standard and detection with flame ionization detector

containing ethylenediamine tetra-acetic acid, citric acid, or heparin as an anticoagulant and/or sodium fluoride as a preservative. Disposable plastic syringes and needles are suitable for obtaining samples and transferring them to appropriate containers containing a suitable anticoagulant and preservative. The skin should be cleaned with soap and water or an alcohol-free swab (e.g., 0.1–0.5% chlorhexidine gluconate solution) before inserting the needle. In our experience, the risk of contaminating blood with alcohol is negligible even after the skin is swabbed with 80 v/v% ethanol; however, to avoid unnecessary battles in the courtroom swabs containing ethanol or isopropanol should not be used before taking blood samples. Ethanol in blood is relatively stable at 4°C for as long as 1 month when tubes are sealed. A negligible amount of ethanol, 0.02–0.03 mg ml<sup>-1</sup> a month, is converted to acetaldehyde due to a non-enzymatic oxidation by oxyhemoglobin. The rate of ethanol loss actually depends on how often and how long the tubes have been opened at room temperature. In our laboratory, the maximum loss of ethanol from blood stored at 4°C, 25°C, and 37°C for 30 min in containers without caps was ~1%, 3%, and 7%, respectively.

Urine is also a good specimen for detecting ethanol because it is easy to obtain and handle. However, the ethanol concentration represents an average value between the last voided time and sampling time. Although ethanol is stable in urine, it is preferable to transfer urine to a container containing sodium fluoride at a final concentration of 1–2% and store at 4°C prior to analysis.

Saliva is used for on-site ethanol testing using commercially available testing devices. Saliva is absorbed in a pad on the test strip under the tongue until it is saturated. The volume of saliva needed for the current commercial tests is small and can be collected in 1 or 2 min or less.

### Dead Persons

Various body fluids, in addition to blood and urine, are available in forensic autopsy cases. These fluids include cerebrospinal fluid, vitreous humor, pericardial fluid, and bile. Samples can be collected with disposable syringes, with or without needles, and transferred to glass containers (5–10 ml) containing sodium fluoride at a final concentration of 1–2% as a preservative. As samples from living persons, the containers should be preserved at 4°C until analysis. Special care should be taken while testing for ethanol in postmortem samples since intestinal bacteria diffuse through the body after death via vascular system and induce putrefaction. In moderate to heavily

decomposed bodies, proliferating bacteria can produce ethanol levels as high as 1–2 mg ml<sup>-1</sup> due to anerobic metabolism of carbohydrates. Unfortunately, this complicates the interpretation of analytical results for ethanol. There is, so far, no definitive method to determine how much ethanol is produced after death. Currently, the most reliable indicator of postmortem ethanol production is n-propanol, which is not found in alcoholic beverages. Bacteria produce both n-propanol and ethanol after death; however, the amount of n-propanol in blood is usually at or less than 1/20 times the amount of ethanol. Thus, if detectable amounts of n-propanol exist in postmortem samples, it is obvious that postmortem ethanol production also occurred. Postmortem ethanol production in vitreous humor and urine is slower than other body fluids. However, it is often difficult to obtain vitreous humor in decomposed bodies. Postmortem ethanol production in urine of diabetic patients is increased due to bacterial fermentation of urinal glucose.

Another issue in postmortem testing for ethanol is postmortem diffusion of ethanol from the stomach into the surrounding tissues. This phenomenon becomes evident within 48 h after death of individuals who died shortly after drinking sessions. In these cases, cardiac blood, blood in the thoracic and abdominal large vessels, pericardial fluid, and bile show falsely elevated levels of ethanol. Femoral venous blood, urine, and cerebrospinal fluid are relatively spared from ethanol diffusion from the stomach. However, vitreous humor is the best specimen of choice due to its anatomical location.

### Breath Alcohol Testing

In 1955, breath analysis for alcohol was first used for traffic law enforcement in the USA. This technique is now in routine use in many countries as a substitute for the invasive blood sampling in apprehended drivers. Police officers can obtain on-the-spot results of breath alcohol tests using portable evidential breath testing devices. The distribution of alcohol between blood and alveolar air obeys Henry's law, which states that at a given temperature, a direct relationship exists between the amount of alcohol dissolved in blood and the amount of it in the alveolar air. Although the blood–breath alcohol ratio is affected by several factors such as the arterial–venous differences in alcohol concentrations during alcohol absorption, hematocrit, body temperature, and pulmonary diseases, it is usually in the range of 2000:1–2300:1. For forensic purposes, the value of 2000:1 is employed in Austria, France, and Japan, the value of 2100:1 in Germany, Norway, Sweden,

and the USA, and the value of 2300:1 in the Netherlands and the UK.

Breath alcohol analysis is also useful for diagnostic purposes especially at the emergency room. Based on bedside results of breath alcohol tests, emergency doctors can determine whether observed symptoms, signs, or injuries are drinking-related.

An erroneous result may be obtained when contaminated breath with residual alcohol from vomiting or eructating in the mouth is delivered. However, these can be avoided by monitoring the subject for ~15 min prior to breath sampling to make sure that nothing enters the mouth. Residual alcohol is rapidly removed by salivary flow, reflex swallowing, and absorption into the buccal mucosa. Analyzing two breath samples from a subject may be another safeguard. The results agreeing within  $\pm 0.02$  g per 210 l are acceptable.

## Chemical Methods

Owing to its volatility, alcohol can be separated from biological samples and subsequently measured using oxidizing agents such as potassium dichromate, potassium permanganate, and osmic acid. For example, the yellow-orange dichromate ion is reduced to the blue-green chromium(III) ion in strong sulfuric acid solution in the presence of alcohol. Widmark in 1922 developed one of the earliest diffusion methods based on this reaction.

### Widmark Microdiffusion Method

Two milliliters of mixed solution of potassium dichromate and sulfuric acid is added to a 50 ml Widmark flask and 0.2 ml of a body fluid is placed in a glass spoon whose stem is fused to the center of a glass stopper that seals the flask. The stoppered flask is heated at 50–60°C for 2 h to allow the simultaneous distillation and oxidation reaction to be completed, and cooled at room temperature. The flask is unsealed and 25 ml of distilled water is added to the flask. After cooling, 0.5 ml of potassium iodide solution is added and precipitated iodine is titrated with 0.01 N sodium thiosulfate using 1% starch in sodium chloride-saturated water as an indicator. The amount of alcohol (mg) is calculated by the following formula:  $0.113 \times (\text{consumed volume (ml) of sodium thiosulfate solution in the sample} - \text{consumed volume (ml) of sodium thiosulfate solution in a diluted intact dichromate solution})$ .

### Conway Cell Microdiffusion Method

A Conway cell is a porcelain dish containing two concentric wells. A biological sample is added to the

outer well and a color reagent (the combined solution of potassium dichromate and sulfuric acid) is added to the inner well. The cell is covered and is heated in an oven for an hour or allowed to remain overnight at room temperature. Ethanol diffuses out of the sample into the center well where the chemical reaction occurs. This color test can be observed visually, making this a simple screening method. Semi-quantitation can be made by preparing standards with known amounts of ethanol and comparing the intensity of color of a sample with the standards. Sample can also be quantified spectrophotometrically at 450 nm.

However, this method is not specific for ethanol. Various alcohols, aldehydes, and ketones that are produced in dead bodies during putrefaction also convert dichromate to the chromic ion and give falsely elevated levels of ethanol.

## Enzymatic Methods

ADH is used to measure ethanol in body fluids. ADH oxidizes ethanol to acetaldehyde in the presence of a coenzyme  $\text{NAD}^+$ , which is reduced to NADH that is measured spectrophotometrically at 340 nm:

Bonnichsen and Theorell in 1951 were the first to use ADH for analyzing ethanol in blood, and for several commercial kits, such as Blood Alcohol UV Test 'BMY' (Boehringer Mannheim) and Alcohol Kit (Sigma), are available for measuring ethanol in whole blood, serum, plasma, and urine by using this method.

### A Representative Spectrophotometrical Method

To a glass centrifuge tube, containing 4 ml of 0.33 M perchloric acid, 0.5 ml of a body fluid is added. The capped tube is vigorously vortexed and centrifuged at 3000 rpm for 5 min. To a test tube containing 4.8 ml of pH 8.7 semicarbazide buffer and 0.1 ml of NAD are added 0.1 ml of supernatant of the deproteinized sample and 0.02 ml of ADH (32 IU or more). The tube is capped and incubated at 37°C for 25 min, and absorption is measured at 340 nm. Distilled water is used as a negative control. Ethanol levels are determined with a standard curve prepared by using known amounts of ethanol.

On-site kits for measuring saliva ethanol are available from Chematics, Inc. (ALCO-SCREEN 02), Roche Diagnostic Systems (On-Site Alcohol) and STC Diagnostics Inc. (Q.E.D. A 150 or 350 Saliva Alcohol Test). All of these kits use the same methodology for detecting alcohol. NADH reacts with

indonitrotetrazolium violet dye (INT) and a hydrogen acceptor to form a highly colored formazan compound:

Sample should be collected at least 10 min after the consumption of food or beverages, and tests are completed within 3 min, according to the manufacturers' instructions.

Automated enzymatic systems are available for measuring ethanol in body fluids for clinical and forensic purposes. EMIT is a popular technique for detecting drugs of abuse in urine, serum, and plasma. EMIT ETS PLUS ethyl alcohol assay was designed for the Syva ETS PLUS analyzer. EMIT is a homogeneous immunoassay which utilizes the enzyme glucose-6-phosphate dehydrogenase activity, instead of ADH, to reduce NAD to NADH. Abbott Laboratories introduced a radioactive energy attenuation (REA) assay for determining ethanol on the TDx analyzer, microprocessor-controlled automated fluorometer used for fluorescence polarization immunoassay for many therapeutically monitored drugs. In the REA method, the enzyme-catalytic reactions of ADH and diaphorase results in the formation of reduced thiazolyl blue dye (MTT), a purple color chromogen that has an absorbance peak at 565 nm. The fluorescence intensity of fluorescein, which is a fluorescent indicator added to the reaction, decreases logarithmically with increasing concentration of reduced MTT.

ADH does not react with methanol or acetone but reacts to a lesser degree with n-propanol, isopropanol, and n-butanol. EMIT is free of interference from small molecular weight alcohols, aldehydes, ketones, and glycols. Automated enzymatic methods are useful for clinical purpose because a large number of samples can be handled in a short time period. In the forensic laboratory, however, chemical methods for determining ethanol in biological samples are not generally used because they are not specific.

## GLC Methods

Gas-liquid chromatography (GLC) is the most commonly used method for the forensic and clinical analysis of ethanol. Cadman and Johns in 1958 first reported a GLC method for determining blood ethanol concentrations. They extracted ethanol from samples prior to analysis by adding equal volume of n-propyl acetate (1 ml) to a blood sample (1 ml) to extract ethanol. No internal standard was used. A fixed volume of extract (35  $\mu$ l) was injected into a GL chromatograph equipped with a thermal

conductivity detector (TCD) and a column containing 28 g of a mixture consisting of Flexol 8N8, diisodecyl phthalate, and poly(ethylene glycol) (PEG) 600 (15:10:3 by weight on 100 g of 42/60 mesh firebrick). The levels of ethanol were determined using a standard curve prepared by adding known amounts of ethanol to blood. Subsequently, other methods have been developed that use protein precipitation, distillation, direct injection, and headspace techniques.

Current methods use direct injection and headspace techniques because they are easy, very sensitive, and reproducible. While the flame ionization detector (FID) is not very sensitive to water, it is very sensitive to organic compounds and is well suited for analyzing biological samples. Generally, nitrogen is used as a carrier gas and chromatographic separations are carried out isothermally at an oven temperature of 80–100°C. Recently, alcohols were analyzed in blood using capillary or wide-bore columns. PoraPLOT Q, a fused silica, was the first capillary column used for analyzing short-chain alcohols. Graphitized carbon coated with 5% Carbowax (= PEG) 20 M or 0.2% Carbowax 1500 was ideal for analyzing short-chain alcohols. However, packed columns dominate the procedures used in forensic laboratories, because capillary columns require more maintenance and strict conditioning compared with packed columns. In addition, capillary columns with bonded phases are vulnerable to water found in body fluids. Moreover, capillary columns are prone to overloading because of less sample loading capacity compared with packed columns. The columns for GLC analysis of alcohols are usually 1–2 m long by 0.3 cm ID and made of glass or stainless steel. Stationary phases commonly used for alcohol analysis are Carbowax or PEG 400, 600, 1000, 1500, or 20 M at a loading of 5–25 w/w% on such a solid support as Carbowax, Celite, Chromosorb, or Shimalite. Porous polymer materials (styrene-divinylbenzene) such as Porapak P and Q have also been used as packing materials.

## Direct Injection Techniques

The easiest and fastest method involves the direct injection of a diluted sample with an internal standard solution into a GL chromatograph. We recommend an ultramicro-method utilizing direct injection. Aliquots of a body fluid and an internal standard, such as n-propanol, are mixed together in equal volumes. A 1  $\mu$ l aliquot of the mixture is injected into a GL chromatograph equipped with a glass column (2 m long by 0.3 cm ID) packed with 0.2% Carbowax 1500 on 80/100 Carbowax C and an

FID. The column is filled with a precolumn glass insert filled with a loosely packed silanized glass wool plug that acts as a trap for the nonvolatile proteins in the sample. Temperatures of injection port and column are 120°C and 100°C, respectively. Ethanol concentrations in body fluids are determined from a calibration curve constructed by plotting ethanol concentration of standard ethanol solution versus peak area ratios of ethanol to the internal standard. In analyzing body fluids obtained from decomposed bodies, 2-butanol rather than n-propanol is suitable as internal standard because n-propanol is produced postmortem in various degrees. Unfortunately, the repeated injection of biological material into the chromatograph causes a build-up of non-volatile substances in the injector and the front end of the analytical column, which causes more maintenance and column replacement. These problems can be alleviated by using the headspace procedure.

### Headspace Techniques

Curry in 1962 first described headspace techniques, which are most common worldwide. Headspace techniques are based on Henry's law, which states that the ratio of a dissolved substance in aqueous solution to the substance in the vapor in a sealed glass vial is constant, depending on temperature. The concentrations of volatile substances, such as alcohols in a body fluid, can be determined by analyzing the vapor, which is in equilibrium with the body fluid, in a sealed glass vial at an increased temperature. A sample of the headspace is removed from the vial using a gas-tight syringe and injected into a GL chromatograph. The following is a procedure for detecting ethanol in body fluids in forensic autopsy cases including decomposed bodies and victims suspected of the existence of alcohols and/or other volatiles.

A 0.5 ml portion of a body fluid and 0.5 ml of an internal standard ( $1 \text{ mg ml}^{-1}$  2-butanol) is placed in a 15 ml glass vial, which is capped with a silicon rubber and sealed with an aluminum cap. The sealed vial is incubated in an aluminum block at 55°C for 15 min and 1 ml of the air phase is injected into a GL chromatograph equipped with a 2 m long by 0.3 cm ID glass column packed with 5% Carbowax 20 M on 60/80 Carbowax B. Temperature of the injection port and detector is 130°C. The column temperature is initially maintained at 80°C for 2 min and then increased to 130°C at a rate of  $10^\circ\text{C min}^{-1}$ . The final temperature is maintained for 1 min. Flow pressure of the carrier gas is 150 kPa. This procedure is summarized in Table 2. In this method, no interfering

peaks appear at retention times for ethanol and the internal standard. Typical gas chromatograms of blood samples from a nondrinker, drinker, and decomposed body free of exogenous ethanol are shown in Figure 1. Additionally, a 1 m long by 0.3 cm ID glass column packed with 25% PEG 1000 on 60/80

**Table 2** An example of headspace GL chromatography for detecting alcohol in body fluids of living and dead persons

Sample preparation	A 0.5 ml portion of a body fluid mixed with an equal volume of internal standard ( $1 \text{ mg ml}^{-1}$ 2-butanol) in a 15 ml glass vial. Sealed with a silicon rubber and an aluminum cap
Incubation	Equilibrated at 55°C for 15 min
Sampling	Approximately 1 ml of headspace vapor drawn using a gas-tight syringe and injected into a GL chromatograph
Analysis	Separated on a 2 m long by 0.3 cm ID glass column packed with 5% Carbowax 20 M on 60/80 Carbowax B. Column temperature programs: 80°C (2 min) at $10^\circ\text{C min}^{-1}$ to 130°C (1 min). Nitrogen used as the carrier gas at a flow pressure of 150 kPa.
Quantitation	Performed by comparing the peak area ratio of ethanol to the internal standard in the sample with that in a standard ethanol solution

**Figure 1** Gas chromatograms obtained from analyses of headspace vapors in equilibrium with blood samples from (A) nondrinker, (B) drinker with ethanol concentration of  $3.34 \text{ mg ml}^{-1}$ , and (C) decomposed body free of exogenous ethanol. 1: ethanol; 2: n-propanol; and 3: 2-butanol (internal standard).

Shimalite is very useful for routine ethanol testing. *t*-Butanol ( $0.2 \text{ mg ml}^{-1}$  in distilled water, 0.5 ml) is used as an internal standard and isothermal analysis is performed at  $80^\circ\text{C}$ . Flow pressure of the carrier gas is 40 kPa. On this column, ethanol elutes right after the internal standard, which completes within 2.5 min. This is advantageous when handling a large number of samples. However, a caution must be exercised because ethanol peak is interfered with peaks of methanol and isopropanol. Results should be confirmed by reanalyzing samples using another stationary phase such as Proopack Q, or Carbowax B containing 5% Carbowax 20 M.

In performing headspace techniques, partition coefficients of analytes vary depending on the sample matrix (matrix effects), which can affect the results. Ethanol distributes in body fluids according to their water contents. If inorganic salts, such as sodium chloride and sodium fluoride, are present in excessive amounts, then the ratio of alcohol in aqueous solution to the vapor decrease (salting-out effects). Utilizing salting-out effects by adding as much as 1.5 g of sodium chloride or potassium carbonate to 1 ml of blood, the sensitivity of the headspace method is enhanced and very low concentration of ethanol can be determined. However, this salting-out step varies among matrices and alcohols, and it does not eliminate matrix effects. The three-carbon *n*-propanol seems to be salted-out more effectively than the two-carbon ethanol. The best way to eliminate matrix effects is to dilute the fluids. However, in routine biological fluids, even if they are decomposed, matrix effects are usually minimal for ethanol and no special steps are required.

Recently, automated headspace GL chromatographs became available. Although they are expensive, the microprocessor control ensures precise thermostating and timing and also automatic unattended injection and analysis of a large number of samples.

## Infrared Spectrometry

Infrared (IR) technology is widely used for determining alcohol levels in exhaled breath. Molecules of ethanol absorb IR energy at several wavelengths such as  $3.4 \mu\text{m}$  corresponding to the stretching frequency of C–H bonds, and  $9.5 \mu\text{m}$  corresponding to the stretching frequency of C–O bonds. Such specific absorption of IR energy allows identification and quantification of ethanol in breath. Normal human breath consists of nitrogen, carbon dioxide, oxygen, vaporized water, and trace amounts of organic volatile substances. Acetone is an endogenous compound, which is considered to be a potential interfering

substance because it absorbs IR energy at  $3.4 \mu\text{m}$ . Elevated levels of acetone may exist in the breath of diabetics and fasting individuals. Acetaldehyde, the first metabolite of ethanol, and industrial solvents such as toluene and xylene also absorb IR energy at  $3.4 \mu\text{m}$ . These compounds have been suggested as potential interfering substances when IR breath testing devices are used to test drunken drivers. However, specificity can be enhanced by measuring IR energy absorption at multiple wavelengths. Intoxilyzer 1400 and 5000 (CMI, Inc.), which appear on the Conforming Products List of the National Highway Traffic Safety Administration (NHTSA), are the most widely employed evidential breath testing devices using IR technology. These devices are equipped with three filters. A  $3.8 \mu\text{m}$  filter is used as a reference wavelength,  $3.47$  or  $3.48$  for alcohol quantification, and  $3.38$ ,  $3.39$ , or  $3.40$  for detection of interfering substances and correction for acetone. Two optional filters ( $3.36$  and  $5.52 \mu\text{m}$ ) are available for enhancing the capability of detecting interfering substances.

## Electrochemical Oxidation/Fuel Cell

Fuel cell technology for detecting breath alcohol was introduced in the 1970s. The fuel cell consists of two platinum electrodes separated by an ion-conducting porous substrate. Alcohol in an exhaled breath sample is converted in the fuel cell to acetic acid, producing two electrons for each ethanol molecule. These electrons produce an electrical current that is directly proportional to the amount of ethanol in the sample. Acetic acid further reacts to form oxygen, carbon dioxide, and water. Since this reaction is slower, acetic acid accumulates in the fuel cell. Thus the time necessary to return to a zero baseline is prolonged after several consecutive analyses of breath samples positive for ethanol. Because the fuel cell can potentially react with other alcohols such as methanol and isopropanol, and with acetaldehyde, it is primarily used for screening tests. Alcolmeter SD-2 (Lion Laboratories, Ltd.), Breathalyzer 7410 (Dräger Safety, Inc.), and RBT IV (Intoximeters, Inc.) are popular fuel cell breath testing devices approved by NHTSA. These devices are suitable for on-site testing because they are handheld, portable, and battery-operated devices. Intox EC/IR (Intoximeters, Inc.), a fuel cell device coupled with an IR detector, is used in evidential breath testing. In this device, a breath sample is first analyzed for ethanol nondestructively by the IR detector and then by the fuel cell. Since the fuel cell is unreactive to acetone, potential acetone interference can be monitored.

## Solid-State Semiconductor Gas Sensor

Breath alcohol screening devices incorporating solid-state semiconductor gas sensors employ Taguchi cells. Taguchi gas sensors are also commonly used in breath alcohol ignition interlock devices. A Taguchi cell uses so-called n-type semiconductor which consists of tin oxide ( $\text{SnO}_2$ ) bead mounted in a ceramic cylinder; n-type means 'negative-type,' a term used to describe an abundance of electrons that carry a negative charge. The bead has a very high surface resistance in fresh air. When exposed to alcohol, the surface conductivity increases in proportion to the concentration of alcohol. Alert J4X.ec (Alcohol Countermeasure System Corp.) is among officially approved Taguchi cell breath testing devices. Intoximeter 3000 (Intoximeters, Inc.) is a Taguchi cell device coupled with an IR detector. The Taguchi cell is more sensitive than the IR detector to acetone and various other combustible gases, and this difference can be used to monitor interfering substances in breath.

## Other Methods

Aliphatic alcohols are easily separated by liquid chromatography (LC) using a reversed-phase column. Unfortunately, LC does not have adequate sensitivity to alcohols, and its application to analysis of ethanol in body fluids has been hindered. Davis *et al.* developed a liquid chromatographic method coupled with an enzymatic method that generated NADH in a precolumn ADH-catalyzed oxidation of ethanol. Since this method is not selective for ethanol, it has only limited value for determining ethanol in body fluids.

Gas chromatography-mass spectrometry is selective and sensitive for measuring ethanol and other alcohols. As a result of its cost and maintenance requirements, it has not been used for routine testing of ethanol in biological fluids. Headspace GLC with FID has sufficient specific, accurate, and easy to detect ethanol in body fluids for both forensic and clinical purposes. In addition, selective ion monitoring (SIM) is also useful for determining trace amounts of endogenous aliphatic alcohols such as ethanol and n-propanol in body fluids.

## Interpretation of Analytical Results

Since the effects of ethanol on a person's mental and physical condition are correlated with its blood concentrations, intoxication is based on blood ethanol concentrations (Table 3). However, some

**Table 3** Blood ethanol concentrations and clinical signs/symptoms

Blood alcohol (mg ml <sup>-1</sup> )	Signs/symptoms
0.5 or less	Subclinical. Slight physiological changes and euphoria
0.5–1.0	Slightly increased blood pressure, increased respiration and heart rate, sociability, talkativeness, self-confidence, and impaired reaction responses, attention and judgment
1.0–1.5	Apparently intoxicated, decreased inhibitions, excitement, emotional instability, and impaired sensory-motor coordination
1.5–2.5	Slurred speech, vomiting, apathy, and impaired sensory-motor activities
2.5–3.5	Inertia, loss of motor functions, impaired consciousness, lethargy, and inability to stand or walk
3.5–4.5	Unconsciousness, abolished reflex, subnormal temperature, and impaired circulation and respiration. Possible death
4.5 or more	Cardiac insufficiency and depressed brain stem function. Death from respiratory arrest

populations are very sensitive to alcohol. For example, some Orientals (Japanese, Chinese, Koreans, Thais, Filipinos, and Malaysians) have a poor ability to metabolize acetaldehyde, which is the first metabolite of ethanol. As a result, acetaldehyde accumulates in their blood, even after they consume a small amount of alcohol, and they experience an intense flushing of their face that can spread to their neck and upper arms. They can also experience throbbing headache, dizziness, accelerated pulse, tachycardia, and difficulties in breathing. Two types of aldehyde dehydrogenase (ALDH), ALDH-1 and ALDH-2, are responsible for metabolizing acetaldehyde. ALDH-2 isozyme is located mainly in the mitochondrial fraction, and it has a low  $K_m$  ( $\sim 1 \text{ mol l}^{-1}$ ), which ensures that a very low concentration of acetaldehyde circulate in the blood. On the other hand, ALDH-1 isozyme, which is located mainly in the cytosol fraction, has a higher  $K_m$  ( $50\text{--}100 \text{ mol l}^{-1}$ ), and it does not effectively metabolize acetaldehyde until higher concentrations are achieved. The ALDH-2 gene exhibits polymorphism:  $ALDH-2^1/ALDH-2^1$  (normal enzyme activity);  $ALDH-2^1/ALDH-2^2$  (extremely low enzyme activity); and  $ALDH-2^2/ALDH-2^2$  (no enzyme activity). Approximately 40% of Japanese people have extremely low ALDH-2 activity and 5–10% completely lack enzyme activity. Therefore, intoxication in this population should be based on analytical results of blood ethanol and their genetic backgrounds.

There are variations in ethanol concentration in blood. For example, ethanol distributes according to water content and serum or plasma contains 12–20% more water than whole blood. Consequently, the serum or plasma concentration of ethanol is 1.1–1.2 times higher than whole blood. Many researchers have tried to correlate blood ethanol concentrations with levels in other body fluids. For example, the ethanol levels in the cerebrospinal fluid, vitreous humor, and pericardial fluid after equilibrium were 1.1–1.3 times higher than levels found in blood. In addition, ethanol concentrations in bile were very similar to blood levels. Urine and blood are routine specimens collected in both living and dead persons. Generally, blood concentrations of ethanol are higher during the absorptive phase and urine levels are higher during the postabsorptive period. For example, urine to blood ethanol ratio is  $\sim 1.3$  during the postabsorptive phase.

As is stated in the 'Sample collection and handling' section of this article, several postmortem factors may affect forensic ethanol testing in dead persons. Special care must be taken when evaluating effects of ethanol from its levels in postmortem fluid samples.

## Introduction

Arson continues to be a serious problem on a global scale resulting in high costs in terms of property loss, injuries, and fatalities. It can be defined as the deliberate and malicious burning of property having three main elements. First, there has been a burning of property. Second, the burning is incendiary in origin, and finally, the burning was started with the intent of destroying the property. The motives for fire-setting behavior have been classified by The National Center for the Analysis of Violent Crime as vandalism,

excitement, revenge, crime concealment, profit, and extremism.

To prove that the crime of arson has been committed, the cause of the fire has to be determined. Arson is a unique crime in that evidence at the scene can be destroyed; however, a systematic investigation may yield sufficient evidence to determine the cause. It is therefore important that every fire scene is treated as a potential arson crime until proof of natural or accidental cause has been established.

## Nature of Fire Scene Evidence

There are many types of physical evidence present at fire scenes. In general, the physical evidence can be divided into four categories:

1. *Transient evidence.* This type of evidence is temporary or short-lived. The most commonly

encountered examples of transient evidence at a fire scene include gasoline or other petroleum distillate odors, chemical odor, color of flame, and the temperature of the fire. This type of evidence is created by the type of combustible materials in the fire, availability of accelerants, and actions of the arsonist (if applicable). Transient evidence at a fire scene is determined by smell and vision.

2. *Pattern evidence.* This type of evidence is produced by a physical contact between the fire and objects or persons. Common burn patterns found at a fire scene include: V pattern (the pattern at the origin(s) of the fire), multiple origin burn patterns, low burn patterns, and the depth and direction of charring. Other patterns that can be observed at the fire scene are glass fractures, concrete spalling, and the presence of 'trailers' (fire promoters from one point to another). It is also worth noting that if a compartment fire goes to flashover then burn patterns can be difficult to interpret.

3. *Conditional evidence.* This type of evidence is produced by an event or action and includes: direction of the smoke stains, the speed at which the fires spread, the amount, type, and degree of melted material, the condition of the electrical system and fuse box, the condition of the fire alarm and/or smoke detectors, and the location of the safe, important documents, and valuables. This type of evidence often can be used to determine the cause of the fire and/or be used to reconstruct the fire.

4. *Transfer evidence.* This is the classical type of physical evidence and is produced by physical contact between persons or objects, or between persons and objects. Transfer evidence may be classified according to the nature of the matter being transferred, such as biological evidence (e.g., blood, tissue, hair, bone, and body fluids), physical impressions (e.g., fingerprints, footprints, toolmarks, handwriting, identifications, and imprints), and chemical evidence (e.g., ignitable liquid, gunshot or explosive residue, drugs, soil, glass, fibers, plastics, metals, or chemicals). Transfer evidence requires additional laboratory analysis to identify the material and to trace its origin. The main objective of the examination of transfer evidence is to provide a link between victim, suspect, and the crime scene.

In theory, all four types of physical evidence can be found at a fire scene. In practice, however, much or all of the physical evidence may be destroyed by the fire itself or by the efforts to suppress the fire.

## Chemical Evidence at the Fire Scene

An accelerant can be defined as an agent used to initiate a fire or increase the rate of growth

or spread of fire. The detection and identification of an accelerant at a fire scene demonstrates that the crime of arson has been committed. Accelerants can be grouped according to their physical state:

1. Gases: e.g., propane, butane, natural gas.
2. Liquids: e.g., gasoline, paint thinners, kerosene.
3. Solids: e.g., gunpowders, flares, high explosives, flashpowder.

The most commonly detected arson means is the pouring of an ignitable liquid with subsequent ignition by a naked flame such as a match. Even though the ignitable liquid is vaporized and consumed in the fire, its involvement can be established by the detection and identification of ignitable liquid residues (ILRs) in fire debris. The most popular ignitable liquids used as accelerants are gasoline and the petroleum distillates. However, there is a wide range of commercial products that are petroleum derived and therefore potential accelerants. The American Society for Testing and Materials (ASTM) has divided ignitable liquids into eight major classes as shown in **Table 1**. Each class (except for gasoline) is further divided into light ( $C_4$ – $C_9$ ), medium ( $C_8$ – $C_{13}$ ), and heavy ( $C_8$ – $C_{20+}$ ) as determined by the carbon number of their constituent compounds. Each class of liquid is characterized by the types of compounds that constitute the major and minor components.

## Properties of Ignitable Liquids

Ignitable liquids do not burn. The important properties of ignitable liquids relate to the generation of a flammable vapor mixture above the surface of the liquid. These are flashpoint, boiling point, and vapor pressure. The flashpoint is the lowest temperature at which the vapors above the liquid form an ignitable mixture. When a liquid is below its flashpoint, ignition of the vapors does not occur. The vapor pressure of a liquid is the pressure exerted by the vapors above a liquid at a given temperature. When the vapor pressure reaches atmospheric pressure then the liquid is at its normal boiling temperature. Above this temperature the liquid will fully convert to vapor. Other important properties are ignition temperature and lower/upper flammable limits (LFLs/UFLs) of the vapor (**Table 2**). Ignition temperature is the temperature needed to initiate the combustion reaction of the vapor/oxidant mixture. For ignition to occur the vapor/oxidant mixture needs to be within the concentration range of the

**Table 1** Ignitable liquid classification scheme (adapted from ASTM E1618)

<i>ASTM class</i>	<i>Examples</i>	<i>Characteristic compounds</i>
Gasoline		Abundant: aromatics Present: alkanes, cycloalkanes, PNAs <sup>a</sup>
Petroleum distillates	Cigarette lighter fluids Paint thinners Kerosene	Abundant: alkanes Present: cycloalkanes, aromatics, PNAs <sup>a</sup>
Isoparaffinic products	Aviation gas Charcoal starters Specialty solvents	Abundant: branched alkanes
Aromatic products	Xylenes, toluene-based products Specialty cleaning solvents Insecticide vehicles	Abundant: aromatics
Naphthenic paraffinic products	Cyclohexane-based solvents/products Lamp oils	Abundant: branched alkanes, cycloalkanes
n-Alkane products	Solvents, pentane, hexane, heptane Copier toners Candle oils	Abundant: alkanes
Dearomatized distillates	Camping fuels Paint thinners Odorless kerosene	Abundant: alkanes Present: cycloalkanes
Oxygenated solvents	Alcohols, ketones Lacquer thinners	Composition may vary
Others – miscellaneous	Single-component products Turpentine products	

<sup>a</sup>PNAs are polynuclear aromatics.

**Table 2** Properties of common ignitable liquids

	<i>Flashpoint (°C)</i>	<i>Boiling range (°C)</i>	<i>Ignition temperature (°C)</i>	<i>LFL (%)</i>	<i>UFL (%)</i>
Gasoline (100 octane)	– 38	34–184	456	1.4	7.6
Naphtha	– 29	162	134–210	1.1	6.0

lower and upper flammable limits, which is known as the flammable range.

as an accelerant may arise if indicators such as multiple points of origin are established or if unusual burn patterns are observed.

## Recognition of Arson Evidence

Fire investigation is carried out to determine the origin and cause of the fire. The fire investigator uses evidence at the scene to try and establish the point at which the fire started, the first fuel ignited, and the source of ignition. Most fuel available in a structural fire consists of pyrolyzable solids. For this type of fuel to be available for combustion, it must first be pyrolyzed, with the greatest degree of pyrolysis occurring where the heat is most intense. By examining structural damage and tracing the burn pattern, the point of origin can be determined. When investigating a fire, suspicion of the use of an ignitable liquid

## Location of Fire Scene Evidence

Since liquids tend to seek the lowest location, the area in proximity to any heavily charred areas must be searched for an ILR. Other likely areas are those that are shielded from the fire and include: floor cracks, under door thresholds, beneath floor coverings, and areas between baseboard moldings and walls.

The investigator samples debris most likely to contain an ILR in sufficient quantity to enable detection and identification. A range of field detection methods are available to assist the investigator in locating fire debris for laboratory analysis.

Olfactory detection is the oldest method used for detecting an ILR at a fire scene. Experienced investigators can successfully detect an ILR; however, the human sense of smell can fatigue and can be overwhelmed by the inhalation of certain vapors. There are also health and safety concerns in inhaling potentially toxic gases and vapors. Specially trained accelerant dogs can detect sub-part per million levels of ignitable liquids against a clean background. Use of a dog reduces the arduous task of searching the entire fire scene by pin pointing areas where an accelerant may have been used. The results of the onsite canine detection may be useful as an investigative aid, but are nonspecific and may not be admissible in court unless the canine findings are confirmed by laboratory testing.

A variety of portable instruments commonly referred to as 'sniffers' are used. They tend to be nonspecific detectors based on the principles of flame ionization and photoionization. More recently portable gas chromatographs and gas chromatographs coupled with mass spectrometers have become available for use at the fire scene. These provide more information about the sample than sniffers but require more training in their use and interpretation of data.

## Collection of Fire Scene Evidence

Any item or debris suspected of containing accelerant residue should be collected in a tightly sealed, clean, and previously unused paint can, a special evidence bag, or a clean glass jar to prevent further evaporation. The container should be of size similar to the amount of debris but should be no more than three-fourths full, leaving sufficient headspace volume for subsequent laboratory analysis. Care should be taken to avoid contamination as this will compromise the value of the evidence. The container should be labeled with the investigator's name as well as the date, department, location, area from which the sample was taken, case number, and description of the item or contents. The chain of custody must be maintained if the evidence is to be used in court.

There are many factors that contribute to the presence of fire debris that has retained an ILR; however, many of these are beyond the control of the fire investigator. The investigator can only sample from what is available at the scene but needs to consider the properties of the matrix in retaining liquid residues. Porous or absorbent materials such as paper, books, carpeting, and fabric can retain a substantial amount of ignitable liquid and should be collected. If liquid is found in the debris, it should be transferred to a small glass vial using a pipette or

absorbed into an absorbent material and placed into a suitable debris container. It may be possible to compare ignitable liquid samples in the possession of a suspect with unevaporated samples obtained at a fire scene.

## Recovery of Ignitable Liquids from Fire Debris

Chemical analysis of fire debris submitted to the laboratory is usually intended to establish the presence of ILRs. The analysis procedure consists of three separate steps: (1) sample preparation – extraction; (2) analysis of the extracted volatiles to yield a chromatographic profile; and (3) data interpretation – identification of the ILR profile by comparison with known products.

Several groups including the Federal Bureau of Alcohol, Tobacco, and Firearms and ASTM have established procedures for the laboratory analysis of the fire debris. All the procedures involve similar strategies for extraction, analysis, interpretation, and classification of ILRs. Of these, the process of recovering the ILR from the fire debris is the most crucial step in the analysis. Traditional methods for recovering ILRs from debris were based on distillation techniques (steam and vacuum) and solvent extraction; however, these have largely been replaced by headspace sampling techniques that provide both sampling and concentration of the ILR vapors and are capable of detecting sub-microliter levels of ILRs.

Headspace methods work by extracting and concentrating volatiles from the debris on an adsorbent material for subsequent analysis. The methods can be divided into passive or dynamic headspace depending on how the headspace is presented to the adsorbent. Each has its own advantages and disadvantages; however, all headspace methods are limited in that they discriminate against high-boiling residues in the matrix. This can be improved by heating the debris and most methods suggest a temperature range with an upper temperature limit set so as to avoid disproportionate recovery of higher molecular mass compounds and thermal degradation of the matrix. Each of these methods will be considered in more detail.

### Passive Headspace – Activated Charcoal Sampling

In this procedure, volatiles from the fire debris are adsorbed onto a suitable substrate such as a carbon-impregnated polymer commonly referred to as the carbon strip method. The process is determined by diffusion of volatiles to the surface of the adsorbent; hence, it is considered to be a passive or static

headspace technique. The container and adsorbent are stored at an elevated temperature of 50–80°C for 2–24 h with the temperature and the duration being determined by the sample. The adsorbent is then eluted with a minimal amount of a solvent such as carbon disulfide, n-pentane, or diethyl ether and the extract is directly analyzed by gas chromatography (GC). This method is now the most widely used.

### **Passive Headspace – Solid-Phase Microextraction**

Solid-phase microextraction (SPME) is a static headspace method similar to the carbon strip method; however, it does not require a solvent desorption stage. Volatiles are extracted from the headspace by absorption into an absorbent polymer such as polydimethylsiloxane (ASTM method E2154). The absorbent polymer is coated onto a quartz fiber that is housed within a needle similar to a syringe needle. The coated fiber is exposed beyond the tip of the needle in the headspace above the fire debris. As with the carbon strip method, the fiber debris sample can be heated to increase the concentration of volatiles in the headspace. Volatiles are absorbed within the polymer with exposure times for routine screening being within the range 5–15 min. The fiber is retracted within the needle and can then be directly inserted into the injector of a gas chromatograph where the volatiles are thermally desorbed from the polymer onto the column. SPME fibers can be reused but appropriate blanks need to be run to ensure that the fiber is clean.

### **Dynamic Headspace**

Headspace from the evidence container is forced into a tube containing an adsorbent such as activated charcoal or a porous polymer such as Tenax. The flow of headspace through the tube can be achieved by either increasing the headspace pressure with inert gas (positive pressure) or by the application of vacuum to the other end of the adsorbent tube (negative pressure). After the extraction process is completed, the container is removed from the heat source and the tube is removed from the holder. This is a potentially destructive method and samples subjected to this treatment may not be suitable for re-analysis. When charcoal is used as the adsorbent, the trapped organics can be eluted by trickling solvent through the tube into a small vial. The eluent may be analyzed directly or evaporated to a smaller volume before analysis. For Tenax, desorption is best achieved using a thermal desorption system that is directly interfaced to a gas chromatograph. To improve the chromatography a two-stage process is employed, in which the volatiles are thermally

desorbed from the Tenax and then collected in a cold trap. The condensate is then rapidly evaporated onto the column.

### **Direct (heated) Headspace**

The simplest headspace procedure does not use an adsorbent material but involves the direct removal and analysis of a volume of headspace (0.1–3 ml) from the evidence container using a gas-tight syringe fitted with a hypodermic needle. The success of this method is dependent on the concentration of volatiles in the headspace as there is a limit to the volume of headspace that can be directly injected into a gas chromatogram. Heating the debris sample can increase the concentration of volatiles sampled; however, the syringe needs to be heated to avoid condensation problems. Although lacking in sensitivity, this technique is often applied as a screening method because of its speed and ease of use.

### **Solvent Extraction Method**

This method can be applied when the adsorptive nature of the matrix may be problematic in extracting a representative sample. The fire debris is placed in a flask and extracted with an organic solvent. The volatile hydrocarbons that are miscible with the solvent are extracted from the debris. Commonly used solvents are carbon disulfide, dichloromethane, pentane, and hexane. The extract is filtered, evaporated to a small volume, and then analyzed. Sensitivity is similar to steam distillation; however, interfering substances such as pyrolysis products are also extracted.

## **Identification of Ignitable Liquids**

The most commonly used techniques in forensic science laboratories to detect and identify ignitable liquids are gas chromatography–flame ionization detection (GC–FID) and gas chromatography–mass spectrometry (GC–MS). GC–FID is ideally suited for ignitable liquid analysis and has been the method of choice since the early 1960s. It is still widely used as a screening method and can be used for identification; however, the latter is now more commonly carried out by GC–MS. Modern capillary GC columns used with temperature programming can provide good resolution of components in short analysis times. Silicone-based stationary phases provide ‘boiling point’ separations for the aliphatic and aromatic hydrocarbons found in petroleum-based ignitable liquids. However, columns based on chemical interactions can separate aromatic components as a distinct group of peaks from aliphatic

components and polar substances from nonpolar substances.

The flame ionization detector is a universal detector and is capable of detecting all the hydrocarbon components of an ignitable liquid. Specific detectors such as an electron capture detector or nitrogen/phosphorus detector can be used to identify trace substances that may be unique to a specific sample.

During the chromatographic separation the sample is separated into its components, and each peak in the resulting chromatogram represents at least one of the components in the mixture. Each class of ignitable liquids is characterized by a specific chromatographic pattern. An unknown ignitable liquid can be identified by comparison of its chromatographic profile with those in a library of known substances obtained under identical analytical conditions.

Figure 1 shows the chromatogram of a medium product range petroleum distillate recovered from fire debris. This is characteristic of a petroleum distillate in that the predominant peaks are associated with a homologous series of *n*-alkanes in a Gaussian distribution with abundant but less significant isoparaffinic, cycloparaffinic, and aromatic compounds also present. These less significant

**Figure 1** Chromatographic profile for a medium product range petroleum distillate.

components can provide a fingerprint for matching chromatograms. Comparison with a test mixture of *n*-alkanes places the ignitable liquid in the medium product range subclass. Comparison with chromatograms of reference ignitable liquids gave a match with a known mineral spirits (paint thinner) product. Such a result indicates that the fire debris contained a petroleum distillate in the medium boiling range, i.e.,  $C_8$ – $C_{13}$  hydrocarbons. Similar criteria should be applied for assigning an ILR to any of the other ignitable liquid classes.

Such a case as shown by Figure 1 is easy to deal with as the analysis has given a chromatogram that has a characteristic pattern of regularly spaced peaks that are well resolved and distinguishable from the background and interfering compounds. Volatiles from fire debris may be present due to an ILR, the composition of the substrate, and pyrolysis products from the action of heat on the substrate. As the FID does not discriminate between these substances, chromatograms can be difficult to interpret. GC-MS provides the chemical information that can be used to distinguish between ignitable liquid components and background interference. High-resolution capillary GC columns give a more complete separation of petroleum distillates that provides more certain mass spectra on which to base component identifications. Pattern recognition may be carried out using total ion chromatograms; however, this approach may suffer the same problems as GC-FID analysis when dealing with the detection of ILR in the presence of interfering components. This can be overcome by extracted ion profiling as petroleum-based ignitable liquids produce several series of gas-phase ions that are characteristic for the major classes of compounds present. The characteristic molecular and fragment ions for each type of compound found in ignitable liquids are listed in Table 3.

Chromatograms for specific ions indicate the possible presence of a specific class of compound, e.g., the

**Table 3** Characteristic ions for the major types of compounds found in ignitable liquids

Compound type	<i>m/z</i>
Alkanes	43, 57, 71, 85
Cycloalkanes and alkenes	55, 69, 82, 83
Alkylbenzenes	91, 105, 119, 133 (molecular ions 78, 92, 106, etc.)
Indanes	117, 118, 131, 132
Alkyl-naphthalenes	128, 142, 156, 170
Alkylstyrenes	104, 118, 132, 146
Alkylanthracenes	178, 192, 206
Alkylbiphenyls/acenaphthenes	154, 168, 182, 196
Monoterpenes	93, 136

alkanes using the ion  $m/z$  57. This also helps in assigning an ILR to ignitable liquid classes. For example, it is possible to distinguish between petroleum distillates, naphthenic-paraffinic, isoparaffinic products, and dearomatized distillates by comparing extracted ion chromatograms of the ions 55, 57, 83, and 105 (Table 4). Major peaks should be identified from the associated mass spectra. Figure 2 shows how extracted

ion chromatograms can be used to profile trimethyl and tetramethyl benzenes in a gasoline. Extracted ion profiles for unknowns are compared to extracted ion profiles obtained from reference ignitable liquids.

Target compound analysis uses specific compounds that are known to be present in an ignitable liquid. Peakarea ratios can be compared against standards to ensure that chromatographic patterns

**Table 4** Use of extracted ions to differentiate between classes of ignitable liquids

Class	$m/z$ 55	$m/z$ 57	$m/z$ 83	$m/z$ 105
Petroleum distillates	Present – lower abundance than 57	Abundant – Gaussian distribution	Present – lower abundance than 57	Present – lower abundance than 57
Isoparaffinic products	Absent	Abundant – n-alkanes absent	Absent or lower amounts than alkanes	Absent
Naphthenic products	Abundant	Abundant – n-alkanes absent	Abundant	Absent
Dearomatized products	Present	Abundant – n-alkane pattern	Present	Absent

match. In addition, visual pattern matching can be made easier by producing target compound chromatograms (TCCs) that are graphical representations of peak areas for the target compounds. Table 5 lists the target compounds used for the identification of gasoline and medium petroleum distillate. While useful, TCCs should not be used alone.

## Interpretation of Results

The type of physical evidence at an arson scene depends on the method used by the arsonist to light the fire. Generally, it falls into three categories: ignition devices; ignitable liquids; and other associated physical evidence such as toolmarks, fingerprints, footprints, blood, hair, and fibers. Examination of ignition devices is carried out mainly for the purpose of identification. Identification of the type of device and the manufacturer may help in providing useful investigative leads. Macroscopic and microscopic examinations are the most common techniques used to examine an ignition device.

The methods for examination of the different types of associated evidence are varied and are covered in other forensic sections of this encyclopedia.

In establishing the presence of an ILR at the origin of a fire scene careful interpretation of the chromatographic data is required. Consideration needs to be given to the chromatographic distortions that can result from the exposure of the ignitable liquid to the fire scene. Components can be lost from the profile at either end of the pattern and there can also be selective loss of components from within the pattern. Loss of the more volatile components is expected due to combustion and exposure of the liquid to heat. Loss of the less volatile components may be due to incomplete recovery from the debris whereas the loss

of specific components may be due to microbiological degradation.

There is also the difficulty of interpreting patterns in the presence of interfering components that can be present in the substrate or that are generated by pyrolysis of these materials as mentioned in the previous section. These components may mask the presence of an ignitable liquid or suggest the presence of an ignitable liquid as many of these substances are common to ignitable liquids and some can chromatograph as a homologous series of peaks and be mistaken for a petroleum distillate.

It is therefore important to have libraries of chromatograms of ignitable liquids in different stages of evaporation and to also have them for substrates and pyrolysis products. Comparison samples obtained from the fire scene can be used to obtain chromatograms of the substrate background and pyrolysis products. Pyrolysis products that are not identified as target compounds can be excluded from target compound chromatograms. When these products appear on the TCC, it may not be possible to identify the ILR if the pattern becomes overwhelmed.

When an ILR has been identified as belonging to a particular IL class it is appropriate to provide examples of commercial products that belong to this class. It may be possible to match the ILR to a particular example within the class. If the analysis is unable to identify the presence of an ILR it does not necessarily rule out that the fire was incendiary in nature. The analyst should also be aware that any ILR found should not be classified as an accelerant as there may be perfectly legitimate reasons for its presence in the debris submitted for analysis.

## Blood Analysis

**C Brandt-Casadevall and N Dimo-Simonin,**  
Université de Lausanne, Lausanne, Switzerland

### Introduction

In this article we deal with the interesting subject of blood analysis in forensic sciences. For historical reasons we give importance to blood group detection. Indeed, even though presently paternity testing and especially blood stains analyses are performed through DNA profile determination, blood groups were for decades the only way of making identifications.

Blood is a biological liquid that represents between 5.5% and 8.0% of the body weight of an individual. It is composed of 60% liquid, or plasma, with the remaining 40% made up of the following cellular elements: erythrocytes, or red blood cells; leukocytes, or white blood cells; and thrombocytes, or platelets.

The plasma contains ~85% water, the remaining 15% being made up of electrolytes, proteins, glucides, and lipids. The plasma proteins are divided into three groups: albumin, fibrinogen, and globulins (three types of globulins are found,  $\alpha$  and  $\beta$ , whose function is essentially the transport of substances, and  $\gamma$ , which principally constitutes the antibodies).

The red blood cells are unnucleated and have a principal function of transport and maintenance of the functional state of the hemoglobin, the respiratory pigment that transports the oxygen and part of the carbonic gas. Hemoglobin is a protein formed from four peptide chains, each one supporting a molecule of hem (a combination of a porphyrin and an atom of iron). In an adult, a major hemoglobin (Hb A) is found in a proportion of 97%, formed from two  $\alpha$ -chains and two  $\beta$ -chains, and a minor hemoglobin (Hb A<sub>2</sub>) represents 3%, formed from two  $\alpha$ -chains and two  $\delta$ -chains. Blood from a newborn (neonate) contains a high percentage (50% at 2 months of age) of fetal hemoglobin (Hb F), composed of two  $\alpha$ -chains and two  $\gamma$ -chains. Certain pathological hemoglobins (S, C, E, and D) probably result from selective mutations that affect the amino acid sequence. These hemoglobin variants are found in very specific subgroups of the population: for example, hemoglobin S is only found in black populations coming from the west of north tropical Africa (sickle cell anemia). Certain illnesses, such as the

thalassemias, will affect the biosynthesis of the hemoglobin chains by mutation of the regulatory genes and do not, therefore, lead to the formation of abnormal chains but to a change in the proportion of the hemoglobins Hb A, Hb A<sub>2</sub>, and Hb F.

The white blood cells are the mobile units of the reticuloendothelial system. There are three different types of white blood cells: granulocytes (which, according to their affinity for stains, are classified as neutrophils, eosinophils, or basophils), lymphocytes, and monocytes.

The platelets are unnucleated cells that play an important role in blood coagulation.

### Blood Preservation and Aging Effects

As a biological material, blood deteriorates rapidly. For analytical purposes, samples must be taken under the most favorable conditions (sterility, cleanliness, container). It must be submitted to immediate treatment in view of the examinations to be conducted; for example, an anticoagulant must be added for certain analyses (blood groups). Some anticoagulants also serve as preservatives (ethylenediaminetetraacetic acid, potassium oxalate, sodium fluoride, etc.) by fixing certain doubly charged cations, inhibiting the action of the complement and other enzymes as well as countering bacterial proliferation. In order to avoid the rapid denaturation of certain substances (e.g., extremely labile proteins), the blood sample must be kept cold: freezing is essential for the proteins and the isoenzymes, while storage at 4°C is necessary to avoid hemolysis in the case of the detection of erythrocyte groups.

When it is a question of bloodstains, the sampling technique will be as important as the storage conditions as far as later examination is concerned. Contamination and high humidity conditions that promote maceration must be absolutely avoided (transport in plastic containers is excluded). A dried bloodstain must be stored frozen for blood group typing. Certain blood characteristics will be preserved if kept cold, even over many years (ABO, Gm), while others will disappear after a much shorter delay.

During preservation, even under optimum conditions, certain enzymes change their electrophoretic profile. It is possible that this results from interactions between the sulfhydryl groups (SH) of some cysteine residues and the glutathione accumulated over the storage period. This effect may be

eliminated by the addition, before analysis, of reductants such as mercaptoethanol or dithiothreitol.

Presently, techniques exist that store bloodstains for the purpose of DNA analysis in a simple and efficient manner. Thus, the FTA Gene Guard system is a method for collecting and storing dried blood samples for DNA testing ensuring a long-term stability of genomic DNA (>5 years) at room temperature. The FTA's filter paper matrix is impregnated with a chaotropic agent that denatures infectious agents and prevents DNA degradation. The blood cells are lysed, and the DNA is linked to the paper matrix. DNA extraction is achieved through successive washing of a paper punch, which removes contaminants and inhibitors.

# Analysis of Blood Components

## Blood Groups

Some blood constituents display, apart from their particular function, the characteristic of being genetically polymorphic, thus permitting the differentiation of individuals. Such is the case with blood groups (ABO, Rhesus, MNSs, Lewis, Kell, Duffy, etc.), the erythrocyte isoenzymes (phosphoglucosaminase (PGM), acid phosphatase (EAP), esterase D, adenylate kinase, adenosine deaminase, glutamate-pyruvate transaminase, glyoxalase, 6-phosphogluconate dehydrogenase, etc.), and the plasma proteins (group-specific component (GC), haptoglobin (Hp), transferrin C,  $\alpha$ -1-antitrypsin, complement component C3, properdin factor B, plasminogen, immunoglobulin groups (Gm and Km), etc.). Meriting a special mention is the group of human leukocyte antigens (HLA), described by Dausset, that exhibits an exceptionally large polymorphism and a remarkable balance in the population.

Some of these groups have the characteristics of being immunogenic, that is to say they provoke an immune response (antibody synthesis, cellular reaction). This explains their medical importance in transfusions and transplantations. But apart from that, the blood groups, by their genetically determined polymorphism, permitted for many decades, on the one hand, paternity testing to be carried out and, on the other hand, the inclusion or exclusion of a person in a criminal case.

As blood groups remain constant throughout life, they provide information that can aid in personal identification. By comparing phenotypes from a child with those of a presumed father, it is possible to determine if there is an exclusion. For this, it is necessary to know the hereditary characteristics and particularities of each group. In the search for

**Table 1** Different types of paternity exclusions

Blood group	Phenotypes		
	Mother	Child	Putative father
EAP	B	BC	B
Group-specific component (Gc)	2-1S	2	1S-1F
PGM	a1	a3-a1	a4-a1
Hp	2-1	1 <sup>a</sup>	2 <sup>b</sup>

<sup>a</sup>Possible genotypes: 1-1 or 1-0 (0 = silent allele).

<sup>b</sup>Possible genotypes: 2-2 or 2-0 (0 = silent allele).

exclusions, it is necessary to take into consideration two fundamental rules.

Rule 1: 'A characteristic found for the child must also be found either with the mother or with the father'. This rule is strict. **Table 1** shows three examples of exclusion according to this rule – for erythrocyte EAP it is essential to know the mother type to exclude the putative father. On the other hand, for the GC and PGM it is possible to exclude the putative father even if the mother phenotype is not known.

Rule 2. 'A child who is homozygotic for a given system cannot have a father who, for the same system, is inverse homozygotic'. This is a strict rule only in the case where the genotype is readily known as it must be possible to exclude the presence of a silent gene (a gene without phenotypic expression). In **Table 1**, we can see one example of exclusion (Hp) according to this rule.

Knowledge of the frequency of occurrence of different phenotypes in each group of a population permits the calculation of paternity probabilities in the case of nonexclusion.

Blood groups are not only found in the blood. For example, ABO antigens may be found in nearly all tissues of the organism as well as in all the secretions (semen, vaginal secretions, sweat, saliva, urine, etc.) for people having the secretor gene (~80% of the population). The same is true for many isoenzymes and certain proteins, which are found in practically all cells of the body. The A, B, and Rhesus antigens appear in the red blood cells of the fetus during the second month of gestation, but in contrast to the Rhesus antigens, the A/B antigens are incompletely developed at birth.

## Blood Group Detection

The erythrocytes groups are detected by means of immunological reactions, of which the most common is the agglutination of antibodies specific to each antigen. The erythrocyte antigens are situated on the membrane of the red blood cells. Depending on the

antibody used for detection (immunoglobulin M (IM) and immunoglobulin G (IgG)) as well as the localization of the antigen on the membrane of the erythrocyte, the agglutination may occur in a sample saline medium at ambient temperature (ABO, Lewis) or require a macromolecular medium at 37°C (Rhesus) or a medium of weak ionic concentration in the presence of an antiglobulin (Duffy by de Coombs test in low ionic strength solution).

The erythrocyte isoenzymes and the plasma proteins are determined by electrophoretic or isoelectrofocalization techniques. These techniques are performed on a large variety of supports (agarose gel, polyacrylamide, acetate sheets). Electrophoresis is a method of separation in an electric field formed using a continuous current with specific conditions for each protein: buffer composition, migration time, voltage, and temperature. Isoelectric focusing is an electrophoretic separation based on migration in a stable linear pH gradient created with the aid of ampholytes. The proteins will migrate and be focused at their pI (isoelectric point). This technique gives better resolution and sensitivity than the former. Detection of protein bands is performed either through specific enzymatic reactions to give fluorescent or chromogenic products or by direct staining with specific protein stains (Figure 1).

The description of Jeffreys *et al.* of the polymorphism that occurs in DNA repetitive base-pair sequences ('DNA fingerprinting') has permitted more informative data to be obtained for the identification of individuals and for paternity testing.

Since the early 1990s, DNA typing for variable number of tandem repeats (VNTR) loci, detected using the Southern method, started being used in complement with blood group analysis in paternity

testing and also in criminal cases. Some years later DNA amplification techniques (polymerase chain reaction (PCR)) for typing of genetic loci also within satellite DNA VNTR and especially STR (short tandem repeats)) stopped relying on the identification of blood groups.

### Hemoglobin

Determination of the hemoglobin variants may give important information in forensic medicine, given that their biosynthesis is genetically determined. Their different electrophoretic mobilities permit easy separation and the data obtained may be applied in cases of disputed paternity and genetic population studies. The detection and quantification of the different hemoglobins may provide information for the detection of certain hemoglobinopathies, which may be interesting in an identification.

### Electrolytes

The quantification of electrolytes, notably through flame photometric (atomic emission) techniques, may have some importance in forensic medicine. Indeed, different authors have reported the possibility of determining the time of death by the increase in concentration of some electrolytes and the decrease in certain others.

### Glucose

The quantification of glucose in the blood, using enzymatic techniques (glucose oxidase) or by ultraviolet (UV)-visible absorption spectrophotometry, may provide some clarification as to the cause of suspicious death (for example, hyper- or hypoglycemic comas). However, the results are only valid if the time between the death and the analysis is relatively short.

## Analysis for Exogenic Substances

This involves the detection of foreign substances in the blood and is a major field in forensic science, forensic toxicology. It includes analysis for different medicinal toxins, narcotics, etc. The determination of blood alcohol concentrations takes on particular importance due to road traffic regulations and the social repercussions of alcohol intoxication.

## Bloodstains

Blood is the one of the most important biological traces and also one of the most frequently studied in forensic cases.

The macroscopic aspect of bloodstains may provide interesting information and is largely

**Figure 1** Properdin factor-B phenotyping performed using thin-layer high-voltage agarose gel electrophoresis and subsequent immunofixation with specific antiserum.

dependent on the age of the stain and the nature of the support on which it is found. Indeed, according to the form and contour characteristics of a bloodstain, it is sometimes possible to determine the trajectory (angle and distance) of the blood droplet that formed the stains. It is also very important to observe accurately and make a full documentation of the bloodstain pattern before sampling. This will ensure that the results obtained from analysis in the forensic laboratory will answer the questions of the criminal enquiry. Three questions will be posed: (1) It is blood? (2) Is the blood human? (3) Who does the blood belong to? The following sequence of tests is performed in the forensic laboratory to identify bloodstains.

### Presumptive Tests

These tests are extremely sensitive but have the disadvantage of not being entirely specific for blood. Such tests are based on the detection of the pseudoperoxidase activity of hemoglobin. The decomposition of a peroxide liberates oxygen, which oxidizes a reduced leukobase, provoking a color change.

Tetramethylbenzidine and *ortho*-tolidine are the most sensitive tests (capable of detecting blood in dilutions of  $1:10^6$  and  $1:10^5$ , respectively), while phenolphthalein and leucomalachite green are less sensitive but more selective.

### Confirmation Tests

These tests serve to detect an entity specific for blood, either cellular components or hemoglobin. The methods employed may be based on microscopic, microcrystallographic, spectroscopic, chromatographic, immunochemical, or immunochromatographic techniques.

Microscopic techniques aim at detecting blood cells, which are identified by their appearance. For this to be possible, the material must be fresh and well conserved. Among the microscopic techniques are those involving a direct search on the material, with the advantage of being nondestructive, while other methods require preparation of the sample. The latter demand a reconstitution and staining of the cellular elements.

Microcrystallographic or microchemical techniques rely on the fact that certain derivatives of hemoglobin have the tendency to crystallize. It is possible to find either crystals of hemein or crystals of hemochromogen (depending on whether the heme molecule is degraded to an iron(II) or iron(III) pigment).

Spectroscopic methods aim to detect the UV-visible absorption spectrum of hemoglobin or one of its derivatives.

Thin-layer chromatographic (TLC) techniques use very small quantities of material. A sample is deposited in the form of a spot and submitted to the action of a solvent (eluant), which causes component substances to migrate on the TLC plate. Detection is performed using a redox reaction with tetramethylbenzidine or *ortho*-tolidine. Positive and negative controls are tested on the same plate. The retention factor ( $k$ ) is used to identify haemoglobin in the sample.

Immunochemical tests (HemeSelect™ commercial kit) use an antihemoglobin antibody in a reverse passive hemagglutination procedure to detect the presence of human hemoglobin with a high degree of sensitivity.

Currently, the most frequently used tests in forensic analysis of bloodstains are immunochromatographic tests (Hexagon OBTI-Test, commercial kit). Initially, these tests were developed to detect the presence of human hemoglobin in stool samples. The kit consists of a testing device and a sample tube with Tris buffer, pH 7.5, with a mild detergent. Monoclonal antihuman hemoglobin (hHB) antibodies conjugated to blue dye particles are able to bind hemoglobin. The resulting antigen-antibody complexes migrate to the test zone, where they are captured with an immobilized second antibody directed against hHB, forming a blue test line (T) to indicate a positive result. Unbound reagents migrate further and are bound in a second line by immobilized antimouse IgG antibodies. This control line indicates proper functioning and correct handling of the test. The test is easy and quick to perform, with a high degree of sensitivity.

These two immunological tests detect the presence of human (and primates) hemoglobin in the stains and can also confirm/inform of the human origin of the blood.

### Bloodstain Origin

Many methods exist for the determination of the origin, human or otherwise, of a particular bloodstain: by the recognition of cellular elements from their morphology and by detecting different characteristics of human hemoglobin (for example, solubility, electrophoretic profile, antigenicity, sequence, etc.). However, tests based on the detection of plasma proteins are the most often employed. A first group is made up of immunological techniques such as antiprotein or antiglobulin sera (Ouchterlony) or immunoelectrophoresis, which has the advantage of eliminating cross-reactions. The value of these tests is irrefutable when they give positive results. They can, however, give false negative results when there is no

quantitative equivalence between the antigens and the antibody (e.g., an antigen is present in too small a quantity) or when the antigens are denatured (e.g., stains treated with certain detergents or proteolytic enzymes).

The second group aims to detect the presence of globulins in the stains using an agglutination method. This technique is easy to apply, very sensitive, and very selective. It involves the inhibition reaction of the particularity of certain incomplete anti-Rhesus (IgG) antibodies to fix onto red blood cells without agglutination occurring. The test demands an initial contact between the sample to be analyzed and a human antiglobulin serum (Coombs serum). O/Rhesus + red cells sensitized with an antiRh antibody are employed as a detection system. If the material contains human globulins, the sensitized red blood cells are not agglutinated as the antiglobulins have been previously neutralized. An agglutination is therefore synonymous with the absence of human globulins in the analyzed material. The human antiglobulin test is more sensitive than the Ouchterlony test. However, given that the latter not only detects globulins but also all the plasma proteins including albumin, it is capable of detecting human material in traces that have been subjected to extreme degradation (albumin is particularly resistant).

The human origin of a bloodstain can also be determined using the immunochemical test (Heme-Select™ commercial kit) and the immunochromatographic test (Hexagon OBTI-test commercial kit) cited above. The latter is the most frequently used in forensic testing.

The origin of a bloodstain can be ascertained in a dot-blot hybridization test using a primate-specific probe such as D17Z1 (= 40 nucleotides complementary to an alpha satellite DNA sequence located on chromosome 17). The DNA sample is denatured, deposited, and fixed on a positively charged nylon membrane. The membrane is first prehybridized in the presence of sodium dodecyl sulfate (anionic detergent) to saturate fixation sites on the membrane and thus prevent nonspecific hybridization of the probe. The hybridization itself is done with a biotin-labeled probe. The bound probe is detected by chemiluminescence using streptavidine/horseradish peroxidase and luminol. Luminol oxidation causes photon emission, which can be detected on X-ray film. A distinct advantage of this test is that it is semiquantitative: in addition to helping establish the origin of the bloodstain, it can also indicate the amount of DNA present by comparing the strength of the signal with known concentration standards (Figure 2). This test is at present the most used in the forensic laboratories to establish the origin of

**Figure 2** Dot-blot. At left, the ladder with spots corresponding to decreasing DNA concentrations. At right, two lines with different samples to be tested.

bloodstains as well as other kinds of forensic samples (saliva, sperm, etc.).

### Bloodstain Identification

**Erythrocyte groups** Historically, the most important by far in forensic practice has been the ABO group as it can persist in a stain up to several years. The determination of antigens for the ABO group was based on indirect agglutination techniques that can only detect ABO phenotypes. Currently, it is possible to determine the ABO genotype using several DNA-based methods using PCR followed by restriction enzyme digestion, single-strand combination polymorphism, or sequencing analysis.

**DNA analysis** Since Jeffreys's discovery of the polymorphism of certain DNA fragments, this analysis has tended increasingly to replace the analysis of blood groups in stains. This is due to the fact that it has the highest discriminating power and specially the fact that DNA is more resistant to degradation than certain proteins. For the analysis of DNA using the Southern blot method, it is necessary to have high molecular weight DNA in a quantity greater than 50 ng. It is for this reason that DNA analysis by PCR amplification is of particular interest. Techniques

using PCR permit us to establish DNA profiles in very small quantities and in samples that are partly degraded.

## Other Data of Forensic Interest

### Sex Determination

When a sample of suspect blood arrives at the laboratory, it may be useful to determine the sex of the donor (for example, in the case of criminal abortion). Low-performance older techniques (search as for the sex chromatin, Barr's body, Y-chromosome fluorescence, etc) and other methods such as the determination of sex hormone levels (progesterone/testosterone) have been replaced by procedures for detecting sites on the X and Y chromosomes using PCR. At present, the sex determination is carried out at the same time that the genetic profile is determined when using multiplex STR kits.

### Determination of Which Part of the Body the Blood Has Come From

This diagnosis is based on a cytological study of the cellular elements found in the stain. The stain must be relatively fresh in order to detect, through microscopic examination, the desquamation cells typical of different regions of the human body.

### Menstrual Blood

This may be identified from its richness in fibrin degradation products, which may be detected using a hemagglutination inhibition method. It is also possible to identify menstrual blood by an analysis for lactate dehydrogenase. This enzyme shows little phenotypic variation between individuals but shows tissue differences that permit the recognition of menstrual blood.

Several authors have reported the possibility of confirming the presence of menstrual blood in stains by detection of messenger ribonucleic acid specific for epithelial cells using reverse transcriptase-PCR.

### Fetal Blood

It may be important in certain cases involving infanticide or criminal abortion to determine whether the blood is of fetal origin. The concentration of fetal hemoglobin or of  $\alpha$ -fetoprotein may be determined, and good results are generally obtained. Liquid chromatography techniques have been described recently for detecting fetal hemoglobin.

## Carbon Monoxide and Cyanide from Fire and Accident

C N Gray, Deakin University, Geelong, VIC, Australia

### Introduction

Carbon monoxide and cyanide compounds are found widely in the environment as a result of natural processes and human activity. CO is produced mainly by incomplete combustion of carbon-based fuels. It is a major toxic component of emissions from natural fires, gasoline (petrol) engines, heating plant, explosives, cooking stoves, open fires, barbecues, cigarettes, etc. The main technological source of CO emissions in advanced countries is the automobile. Concentrations in urban air are typically of the order of a few parts per million by volume (ppm), while concentrations in gasoline engine exhausts can be up to ~8% by volume (80 000 ppm; at normal temperature 1 ppm CO is  $\sim 0.9 \text{ mg m}^{-3}$ ). Diesel engines have much lower exhaust concentrations (up to ~0.1%, 1000 ppm). Mainstream cigarette smoke can contain ~5% (50 000 ppm). The CO concentration in the air in dwellings equipped with gas stoves can be several ppm. Human exposure to CO is usually highest among people directly exposed to combustion gases as a result of un-vented space and water heaters, leaking flues, gas stoves, portable electrical generators, automobiles running within closed garages, and direct inhalation of tobacco smoke. There is also toxicologically significant exposure among some working populations, such as coke oven workers, miners, and underground car park attendants.

Inorganic cyanide compounds, such as sodium or potassium cyanide, are released into the environment by a number of industrial processes including mining, electroplating, and metal treatment. Solutions of cyanide salts are used to leach gold, silver, and some other metals from their ores, a practice that can result in large volumes of cyanide-contaminated water and solid waste. Cyanide compounds are used in gold, cadmium, and zinc electroplating. Some metals are hardened by heating them in molten cyanide salts. Cyanide compounds have many other applications including in the manufacture of pigments, in photography and etching, and as pesticides for the control of rabbits, rats, and termites. Hydrogen cyanide is used as a feedstock in the production of a range of chemicals including adiponitrile (used in the manufacture of nylon) and methyl

methacrylate. It is also used as a poison for the control of rodents and other pests; for example, in the fumigation of grain stores. Hydrogen cyanide can also be released during fires involving nitrogen-containing polymers such as polyurethane, nylon, acrylonitrile, and ABS (acrylonitrile-butadiene-styrene) and can be a danger to fire fighters and others exposed to the smoke of such fires. The main source of cyanide in urban air is the internal combustion engines where it is produced by free-radical reactions involving nitrogen from the atmosphere. Coal and some petroleum fuels contain organic nitrogen compounds that can also produce cyanide during combustion, as does tobacco. Significant amounts of cyanide are produced by microorganisms and insects such as millipedes. Cyanide or its precursors (such as cyanogenic glycosides) occur in many plants including cassava, bitter almonds, sorghum, and lima beans.

Human exposure to cyanide can result from inhalation of hydrogen cyanide gas or inhalable dusts of cyanide compounds, the ingestion of cyanide in water or food, or from unintentional hand to mouth transfer in contaminated environments. Away from cities and industry the background air concentration is  $\sim 0.2 \mu\text{g m}^{-3}$ . Concentrations in occupational settings can be several parts per million (as HCN) or several milligrams per cubic meter of air. Typical surface waters uncontaminated by industrial activity can contain cyanide in concentrations up to  $\sim 5 \mu\text{g l}^{-1}$ . Tap water can contain  $\sim 0.5\text{--}0.8 \mu\text{g l}^{-1}$  of cyanogen chloride (produced during chlorination). Wastewaters from mines or industry can contain up to several hundred milligrams per liter. Foodstuffs can contain cyanide or cyanogenic compounds in a wide concentration range: cereals, from  $\sim 1$  to  $500 \mu\text{g per kg}$ ; lima beans, as much as  $3 \text{ g per kg}$ . Cooking tends to reduce or destroy the cyanide content of food.

### Toxic Effects

It is estimated that there are tens of thousands of cases of accidental CO poisoning in the US each year, of which ~600 are fatal, and there are ~2000 cases of suicide utilizing car exhaust emissions. CO owes its toxicity largely to its affinity for the oxygen transport sites in red blood cells thereby interfering with normal oxygen transport to the tissues. CO has about 240 times greater affinity than oxygen for hemoglobin and readily displaces it. About 80% of the CO binds to hemoglobin and 10–15% to

myoglobin in muscles. About 5% binds with the cytochrome enzymes in cells responsible for producing energy from glucose oxidation, thus causing cytotoxic hypoxia. CO can cross the placental barrier and affect the unborn child of an exposed pregnant woman. It is not significantly metabolized and is mainly exhaled unchanged, although ~1% is converted to carbon dioxide. It has an excretion half-life of ~3–4 h for a resting subject breathing air. This can be shortened by the administration of oxygen. CO is also produced endogenously during normal metabolic processes resulting in a background carboxyhemoglobin concentration of up to about 1.2%. CO can also be produced by the metabolism of other substances including dichloromethane (used as a paint stripper). The toxic effects include cardiovascular and neurological damage, the severity of which depends on both the exposure concentration and duration. Concentrations above about 2000 ppm in air are usually fatal after a short time while 1200 ppm is classified as 'immediately dangerous to life or health'. Exposure to about 500 ppm over several hours can result in headache, confusion, and possible collapse; 50 ppm can be tolerated over many hours by healthy individuals with minimal symptoms. Shorter exposure periods cause less effect because it takes some time for the carboxyhemoglobin to equilibrate with the environmental CO concentration. For healthy individuals 200 ppm is generally considered safe over an exposure period of 15 min, 100 ppm for 30 min, and 60 ppm for 60 min. Most countries have set occupational exposure limits of 50 ppm for 8-h daily average exposure as well as short-term exposure limits (refer to local regulations).

Cyanide is recorded as the direct cause of death in only a few tens of cases in the US each year, but it is probably a contributory cause in many other cases such as the 5000–10 000 deaths due to smoke inhalation. It has, of course, been used for legal execution in the US for many years. Cyanide occurs naturally in the blood at concentrations up to about  $10 \mu\text{mol l}^{-1}$  ( $260 \mu\text{g l}^{-1}$  as  $\text{CN}^-$ ). Elevated levels can be cleared from the body quite quickly with a half-life of about 30 min. Cyanide uptake can occur by inhalation of hydrogen cyanide gas or cyanide dust, and by the ingestion of cyanide or cyanogenic compounds. In the acid conditions of the stomach cyanide compounds react to produce hydrogen cyanide, which is rapidly absorbed. Cyanide is transported in the blood stream to all parts of the body where it enters the cells and blocks the cytochrome *c* enzyme responsible for transferring the energy produced by the oxidation of glucose into chemical energy in the form of adenosine triphosphate. This mechanism is similar to

the cytotoxic effect of CO except that oxygen transport to the tissues is not restricted; only its utilization by the cells is impaired. The primary effects of cyanide poisoning are on the nervous system, partly because nerve cells have little energy reserve when oxidative metabolism is blocked. Hydrogen cyanide gas at concentrations above a few hundred parts per million are generally fatal. Death has been reported following exposure to ~200 ppm for 10 min or ~130 ppm for 30 min. The average fatal oral dose in humans is ~100 mg as CN ( $\sim 1.5 \text{ mg per kg}$  of body mass). The lowest fatal human dose is thought to be ~40 mg. Occupational exposure limits in various countries are typically between 2 and 5 ppm for hydrogen cyanide and about  $2\text{--}5 \text{ mg m}^{-3}$  (as  $\text{CN}^-$ ) over an 8-h day. In addition, ceiling limits have been established that should not be exceeded at any time (refer to local regulations).

## Sampling and Analytical Methods

### Carbon Monoxide

Sampling and analytical methods are available for very high concentrations of CO in exhaust pipes and flues and very low concentrations in the ambient atmosphere. These include colorimetric devices, electrochemical analyzers, infrared spectrometers, and gas chromatographs. A sample may be collected in a suitable container for analysis at a later time in the laboratory, or the analysis may be carried out onsite. Sampling containers can be canisters or either Teflon or Tedlar bags that can be filled using manual or battery-operated pumps. In many parts of the world new houses are now required by law to have smoke detectors and CO detectors are also becoming mandatory in some places. Detectors used for such purposes need only be calibrated at the set point of the alarm system, but must be reliable and must be certified by the relevant authorities.

**Detector tubes** A simple and relatively inexpensive measurement method involves the use of calibrated stain-length detector tubes such as those produced by Draeger, Kitagawa, Gastec, MSA-AUER, and others. CO detector tubes often rely on the reaction of CO with iodine pentoxide, which produces a purple colored iodine stain. The detector tube carries a scale calibrated in parts per million and the length of the color stain that develops after the required number of pump strokes corresponds to the concentration of CO in the sample:

Detector tubes are available for CO covering a measurement range from a few ppm to several thousand ppm. Some are suitable only for short-term sampling whilst others may be operated over a period of hours with the aid of a low-flow battery operated sampling pump or by passive diffusion.

**Electronic and electrochemical detectors** There are several different types of electronic or electrochemical detector for CO of which metal oxide semiconductor (MOS) sensors and electrolytic cells are the most common. In MOS detectors CO is oxidized on a heated tin oxide semiconductor where surface-adsorbed oxygen oxidizes gases such as CO and hydrocarbons producing electrons that enter the conduction band of the semiconductor thereby reducing its resistance:

MOS detectors can be used in alarm systems to trigger a warning when dangerous concentrations of CO (or other reducing gases) are present, or in quantitative instruments. They are not specific to CO and interference can result from either reducing or oxidizing gases. It is possible to make them more selective by using a filter to prevent interfering gases from reaching the detector, or by doping the detector with catalyst metals so that they can be operated at lower temperatures at which some gases do not interfere. They have relatively high power requirements and continuously operating variants are usually connected to mains electricity.

Another type of CO detector uses porous platinum electrodes to catalyze the oxidation of CO at the anode of an electrolytic cell:

Usually the cell is held in a semiporous membrane that allows CO to diffuse through. The cell reactions produce a current that is proportional to the CO concentration in the surrounding air and can be used to give a direct reading of concentration or trigger an alarm at a preset value.

**'Biomimetic' detectors** Another relatively simple device for detecting CO utilizes the reversible reaction of CO with an iron(II) compound held in a porous matrix to produce a color change that can be measured optically. The iron compound may be a synthetic porphyrin, which in a sense mimics the biochemistry of hemoglobin; hence these detectors are

referred to as biomimetic. These devices are most commonly used in dwellings as CO alarms in a smoke/fire alarm system. They are relatively slow to respond to changing CO concentrations and some early models had a tendency to progressively retain their color change and provide false alarms.

**Infrared analyzers** Some fixed point and portable CO analyzers used in industry employ infrared spectrometry or nondispersive infrared (NDIR) photometry. CO strongly absorbs infrared radiation at a wavelength close to  $4.6\ \mu\text{m}$  and can be measured in the presence of some other gases such as water vapor and carbon dioxide. These instruments have a gas cell that allows a beam of radiation to pass through the sample gas either once, or multiple times by reflection from mirrors. A typical portable infrared spectrometer used for gas analysis is the Foxboro MIRAN SapphIRe. This contains a gas cell that by multiple reflections from internal gold-plated mirrors can achieve a single beam pathlength of up to  $12.5\ \text{m}$ . Wavelength selection is by a variable interference filter giving moderate resolution, plus a number of fixed wavelength filters for specific gases including ones centered on  $4.5$  and  $4.7\ \mu\text{m}$ . They are capable of measuring CO down to concentration in the sub-ppm range and give a continuous reading with an averaging time of about  $10\ \text{s}$ . NDIR instruments are similar in many respects to simple single beam gas spectrometers. They may have specific or narrow wavelength detectors and many have narrow band-pass filters to select the wavelength of the beam. Sensitive NDIR instruments can detect sub-ppm concentrations of CO.

**Gas chromatography** For measuring very low background levels in ambient air gas chromatography is more sensitive than most of the preceding methods. This can be automated to give a semicontinuous analysis *in situ*, or samples can be collected in containers, canisters, or inert bags, returned to the laboratory, and transferred to the gas chromatograph by gas-tight syringe. Most of the carbon dioxide present is first removed by alkaline permanganate and residual carbon dioxide and hydrocarbons are removed in a 'stripper column'. CO is then separated from any methane and other gases and vapors present in the sample by passing it through a second column. The eluant from the column is then passed over a catalyst, where CO is reduced to methane, and then passed to a flame ionization detector. An alternative method uses a helium glow discharge ionization detector (DID).

**Calibration** Calibration of analytical instruments for CO is usually achieved using commercially

available calibration gas mixtures. Several of the major suppliers of industrial gases sell certified calibration gases and some such mixtures are also available through the Occupational Safety and Health Administration (OSHA) laboratories in Cincinnati, USA.

**Biological monitoring** It is often useful to be able to measure the CO in the blood of an exposed person, for example, to investigate occupational exposures, to assist in diagnosis and treatment after accidental over-exposure, and in forensic investigations following a suspicious death. If a blood sample can be obtained it is possible to measure the carboxyhemoglobin concentration directly by spectrophotometry. For example, the blood sample is substantially diluted in sodium carbonate solution, with the addition of sodium hydrosulfite solution and sodium hydroxide. The absorbance is then measured at wavelengths of 532 and 558 nm and the carboxyhemoglobin ratio is calculated from these values. There may be some complication in postmortem samples because of the presence of other modified forms of hemoglobin including methemoglobin (iron(III)) and sulfhemoglobin. Carboxyhemoglobin concentration can also be measured using gas chromatography by liberating the CO and collecting it in a headspace device. Where it is not convenient to obtain a blood sample, for example, during routine occupational monitoring, exhaled breath analysis is usually a satisfactory substitute. A breath sample can be collected in a bag or tube using an exhalation valve to collect the end-tidal sample. The sample can later be returned to the laboratory for analysis by one of the techniques described previously. Alternatively, a portable instrument can be used to analyze the exhaled breath directly. It is important to consider the kinetics of uptake and excretion (toxicokinetics) when interpreting the results of biological monitoring; for example, a moderate concentration in blood many hours after exposure could indicate a very high initial concentration.

## Cyanide

There is often a need to monitor cyanide in air, water, solid waste, food, and other environmental samples. The cyanide present in these samples may include free (noncomplexed) cyanide such as hydrogen cyanide (or hydrocyanic acid in water solution), cyanogen ( $C_2N_2$ ), cyanogen chloride, cyanide salts, or complexed cyanide such as metal-cyanide complexes of iron, nickel, copper, mercury, silver. Complexed cyanides are less toxic because they are less bioavailable, but they may break down producing free cyanide, for example, as a result of the ultraviolet radiation in daylight. Analytical techniques for free

cyanide may not detect complexed cyanide, but methods are also available for total cyanide, for example, by first distilling the sample with phosphoric acid and, if necessary, ethylenediaminetetraacetic acid to form hydrogen cyanide which is then collected in an alkaline solution.

Direct methods of analysis are available that may be used *in situ*, or samples may be collected for subsequent analysis in the laboratory. Liquid samples may be collected in glass or plastic containers provided that the pH is kept at about 11 or greater in order to prevent the loss of hydrogen cyanide gas. If the pH falls, for example, because of the uptake of carbon dioxide from the atmosphere, significant losses can occur during transport and storage. Air samples can be collected in a liquid-filled bubbler (impinger) containing alkali solution. Alternatively, a filter can be used to collect particulate cyanide compounds while the hydrogen cyanide gas passes through the filter and can be collected in an alkaline bubbler or on a silica gel or soda lime sampling tube; the particulate cyanide is then washed from the filter with an alkaline solution and the trapped gaseous cyanide is washed from the tube in the same way.

**Detector tubes** As with CO, hydrogen cyanide in air can be measured conveniently with reasonable accuracy by stain-length detector tubes. A typical reagent mixture is mercuric chloride and methyl red indicator. The hydrogen cyanide is converted to mercuric cyanide with the production of hydrogen chloride, which produces a pH change and as a result the indicator changes color to red:

The tubes generally have a precleanse layer to remove interfering substances such as acid gases. These tubes are not suitable for particulate cyanide. Detector tubes are available for HCN covering a measurement range from a few ppm to several hundred ppm. Some are suitable only for short-term sampling whilst others may be operated over a period of hours with the aid of a low-flow battery operated sampling pump or by passive diffusion. There are also detector tubes for cyanogen chloride.

**Ion-selective electrodes** Ion-selective electrodes function as a half-cell that in the presence of certain ions produces an electrical potential that can be compared to a reference cell. The selectivity is determined by the nature of the membrane separating the electrode from the test solution. Membranes used in cyanide ion-selective electrodes are usually of the

insoluble inorganic salt type. These electrodes are relatively specific, but interference can result from chloride, bromide, and iodide ions. Metal ions can also be a problem if they can form complexes with cyanide, for example, cadmium, zinc, silver, nickel, copper(I), iron, and mercury. Ion-selective electrodes are relatively cheap and do not require expensive or complex peripheral equipment. They can also be used in potentiometric analysis; the cyanide in solution is titrated against hypochlorite until there is no further change in electrode potential. The hypochlorite forms a complex with the cyanide so that it is no longer available to the detector.

**Spectrophotometry** There are numerous spectrophotometric methods for the determination of cyanide including the pyridine-benzidine method, the pyridine-pyrazole method, and the pyridine-barbituric acid method. As an example, in the latter method the pyridine-barbituric acid coupling agent produces a complex with cyanide that adsorbs principally at a wavelength of 580 nm. This method is frequently used for the measurement of airborne hydrogen cyanide in industrial air. The hydrogen cyanide is collected in an alkaline bubbler, while any particulate cyanide is collected on a prefilter. With a 3 l air sample the range of quantitation is about 0.3–235 ppm ( $\sim 3$ –260 mg m<sup>-3</sup>). In water samples, this method has a lower limit of detection of about 0.02 mg l<sup>-1</sup>.

**Gas chromatography** Gas chromatographic methods for cyanide usually involve using headspace techniques to detect hydrogen cyanide with the use of a nitrogen-phosphorus detector (NPD) or electron capture detector (ECD). Total cyanides can be analyzed in this way after conversion to hydrogen cyanide.

**Flow injection analysis** A standard method of cyanide analysis employs flow injection following ligand exchange and amperometry. The sample is pretreated with ligand exchange reagents in order to release the cyanide from any metalocyanide complexes in which it may be bound. The treated sample is then analyzed by flow injection analysis. Hydrochloric acid converts the cyanide into hydrogen cyanide, which can diffuse through a membrane and dissolve into an alkaline solution. The resultant cyanide ions are measured amperometrically.

**Biological monitoring** As in the case of CO, it is often useful to be able to measure the cyanide in the body tissue of persons suspected of being exposed or poisoned. For cyanide this is possible using tissue, blood, or urine samples. Cyanide is converted in the body to thiocyanate and this may be analyzed as an

alternative to the cyanide itself. Blood or urine samples should be analyzed as soon as possible after collection to minimize biochemical changes that can alter the concentration of cyanide. Bacterial activity, if unchecked, can produce cyanide in the samples during storage. A suitable technique for cyanide in blood analysis is headspace gas chromatography using either an electron capture or nitrogen-phosphorus detector. Spectrophotometric analysis using a suitable reagent, such as pyridine-pyrazolone, is another option. Urine analysis is also possible using spectrophotometry. In this case it is usual to analyze both the cyanide present and its thiocyanate metabolite, for example, by bromination and treatment with pyridine-*p*-phenylene diamine. In postmortem cases tissue samples can be taken as well as stomach contents to analyze for any unabsorbed cyanide or cyanogenic materials.

In fire victims it is not uncommon to find both CO and cyanide. The amounts that are detected can often shed light on the circumstances of the death. The collection and analysis of the samples should be carried out as quickly as possible as the concentration of CO in blood gradually falls while that of cyanide might increase with time.

### Introduction

DNA analysis is now a basic tool in the establishment of links between biological evidence and comparison samples. It has reached such a widespread use and its power is so impressive that it is probably the best-known forensic analytical method in the general public. Because of the need of high-tech instruments and sophisticated analysis kits, standardization has been surprisingly quick to come, favored by the almost monopoly of a couple of providers in this field. As a consequence, forensic DNA analysis is being practiced worldwide using almost identical tools and protocols.

### DNA Polymorphisms

The DNA sequences of any pair of individuals are almost identical. There is, however, a large number of small differences that allow the remarkable variety of mankind. The elements of interindividual variability are also called polymorphisms. Any polymorphism used for forensic identification purposes is called a marker, and the variants at the polymorphic positions are called alleles.

Polymorphisms may come from minor differences at single nucleotide levels. These are called single nucleotide polymorphisms (SNPs) (Figure 1). It is

estimated that there is on an average one SNP for every 500 nucleotides. Another source of variability comes from the repetitive sequences. These are made up of a nucleotide sequence (the repeat unit), repeated in tandem like a series of identical beads on a necklace (Figure 1). The repeat unit can be from two to more than 100 nucleotides long. The polymorphism comes from the extreme variation in the number of repeats. The alleles then differ by their size (length polymorphism) and get their name from the number of repeats they possess. When the repeat unit is larger than six-nucleotides long, the repetitive sequence is called a minisatellite or VNTR (variable number tandem repeat). When it is six-nucleotides long or less, the repetitive sequence is called a microsatellite or STR (short tandem repeat).

There is a huge reservoir of thousands of repetitive sequences in the human DNA that can be used as markers. The VNTRs have been the markers of choice for DNA profiling from 1986 to ~1995, through the use of a method called Southern blotting or restriction fragment length polymorphism typing. Nowadays, the DNA-profiling techniques mainly focus on STR markers, and SNP analysis begins to gain some importance.

### DNA-Profiling Procedures

#### Multiplex PCR Analyses of STRs

Virtually all the forensic DNA analyses performed worldwide are multiplex polymerase chain reaction

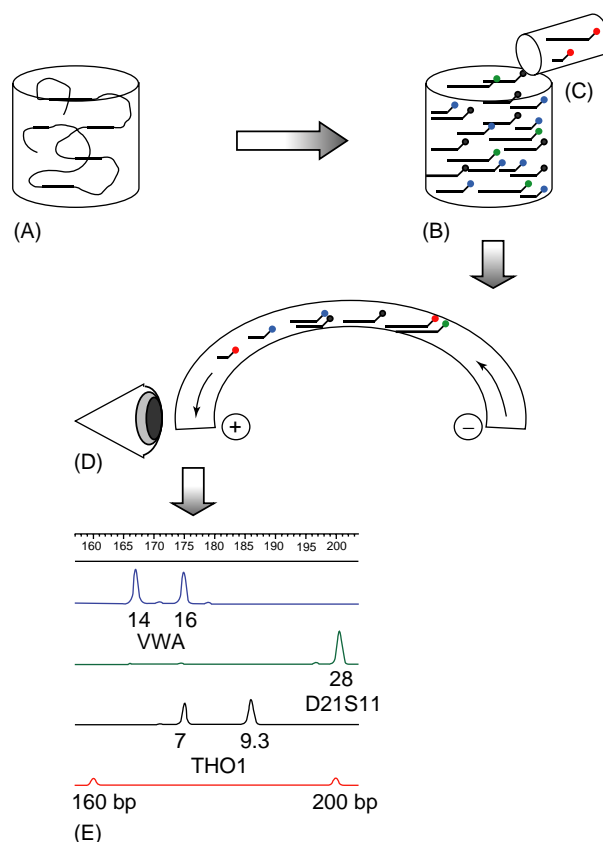

**Figure 1** Schematic presentation of the DNA from two individuals and zoom on a region of their DNA to show that DNA is a linear molecule made of nucleotides, and to illustrate the two main types of polymorphisms used in forensics: the short tandem repeats (STRs) and the single nucleotide polymorphisms (SNPs).

(PCR) analyses of STRs. A basic requirement toward any forensic analysis is a high sensitivity. DNA analysis in forensic science as well as in laboratory medicine has reached a remarkable sensitivity through the use of the so-called PCR. PCR is an ingenious DNA amplification method that cyclically reproduces the natural DNA replication process. Each cycle consists of (1) a denaturation step where the two DNA strands are separated by heating, (2) an annealing step where, after cooling, two short synthetic DNA strands (the primers) are hybridized on both sides of the DNA fragment to be amplified, and (3) an elongation step where a DNA polymerase adds nucleotides to the primers to synthesize the DNA strands complementary to the template DNA. Since the newly synthesized DNA strands can serve as templates for the next PCR cycles, each cycle leads to the doubling of the number of copies of the target sequence. The result of many cycles is millions of copies of the DNA fragment delimited by the primers. The use of a heat-stable polymerase has rendered the whole process very easy and has allowed automation. The nature of PCR makes it naturally extremely sensitive, with a theoretical detection threshold of one molecule! The primers allow the amplification to be highly specific for the desired targets. By using several primer pairs in the same tube, several STRs can be amplified simultaneously; this is called multiplex PCR.

At the end of multiplex PCR amplification, the amplification products of the targeted STR markers must be analyzed by electrophoresis to make visible the nature of the alleles at each marker (Figure 2). Electrophoresis is a separation method for charged molecules, that allows them to get separated because of their varying mobility when they move under the influence of an electric field. DNA fragments are negatively charged molecules and they move toward the anode of the electric field at a speed inversely correlated to their size. The alleles of an STR can thus be separated from each other. The detection of the alleles is rendered simple by using primers labeled with a fluorescent dye. In most laboratories, the electrophoresis is done in capillary electrophoresis instruments that are fully automated. Some are equipped with an array of 100 capillaries, allowing a corresponding number of samples to be analyzed in parallel with a throughput capacity of more than 2000 samples a day.

With an adequate choice of STRs and primers it is possible to analyze simultaneously several STRs displaying alleles in different size ranges. If any overlap of the size ranges is excluded, it is then easy to attribute any allele detected to the correct STR, and to identify its name. By using different fluorescent dye

**Figure 2** A schematic view of multiplex PCR analysis of STRs. In a test tube, some STRs from the sample's DNA (A) are amplified by PCR (B) using fluorescent-labeled primers. After the addition of an internal standard (red-labeled fragments) (C) the DNA fragments obtained at the end of the PCR are separated by capillary electrophoresis according to their size (D) and detected at the end of the capillary. Each peak (E) is then electronically labeled with the name of the corresponding allele. The profiles in blue, green, and black present the alleles detected for the STRs VWA, D21S11, and THO1, respectively. The red profile displays two peaks from the internal standard.

labels, even STRs having alleles in the same size range can be analyzed in multiplex, thus allowing the design of complex multiplex STR analysis kits analyzing simultaneously more than 15 STRs.

What is now called a DNA profile is the result of the analysis of a set of STRs. Two DNA profiles are only comparable if the set of STRs analyzed includes at least a few STRs in common. The key to comparability is standardization. An excellent degree of standardization has been reached worldwide. The US professional organizations have defined a set of 13 STRs that have been considered as obligatory for the US forensic labs. In Europe, there are seven STRs obligatory and they all belong to the set of 13 STRs adopted in USA (Table 1). The companies marketing forensic DNA analysis kits have designed kits to satisfy these convergent needs. As a consequence,

**Table 1** Description of the STRs most frequently analyzed

<i>Name of the STR</i>	<i>Length of the repetitive element</i>	<i>Chromosome location</i>	<i>Allele range</i>	<i>Discrimination power (%)</i>
THO1	4	11	4–13.3	91
VWA	4	12	9–25	94
D21S11	4	21	26–34	95
FGA	4	4	13–51.2	96
D18S51	4	18	8–27	97
D8S1179	4	8	5–19	93
D3S1358	4	3	11–20	92
TPOX	4	2	6–16	80
CSF1PO	4	5	6–15	87
D16S539	4	16	5–15	92
D7S820	4	7	6–15	94
D13S317	4	13	7–15	92
D5S818	4	5	7–16	85
D2S1338	4	2	15–28	97
D19S433	4	19	9–19	92
Penta E	5	15	5–24	97
Penta D	5	21	2.2–17	94

Note: The length of the repeated element is expressed in number of nucleotides and the power of discrimination is calculated for a Caucasian population. The first seven STRs correspond to the minimum European set and the first 13 STRs correspond to the US standard set.

all the kits available on the market offer almost identical sets of STR markers.

A DNA profile appears like the one displayed in **Figure 3**. For each STR, the individual displays a pair of alleles in the form of a pair of peaks. One allele of the pair comes from the mother of the individual and the other allele comes from the father. The two alleles being different, the individual is called heterozygous. A single allele may sometimes be detected for the STRs for which the sample is homozygous, having inherited the same allele from both parents. The DNA profile can be summarized as the list of alleles detected for each STR. The probability that two unrelated individuals taken at random will display different DNA profiles for a set of 15 STRs (the power of discrimination) is quasi-100%. On the contrary, the chance that two unrelated individuals taken at random share a common profile (the random match probability) is usually below  $10^{-15}$ . Such a low number demonstrates how powerful the DNA profiles are. But it reaches the limits of what can be accurately calculated without having to make risky assumptions about the genetic structure of human populations and particularly about the degree of independence of the alleles. Indeed, the random match probability is obtained through the multiplication of the estimated frequencies of the individual alleles of the DNA profile; this multiplication assumes independence of the events, a characteristic that is not completely warranted in the real world. As a consequence, the random match probabilities calculated cannot be defended as correct to the last digit. Only the approximate order of magnitude is correct.

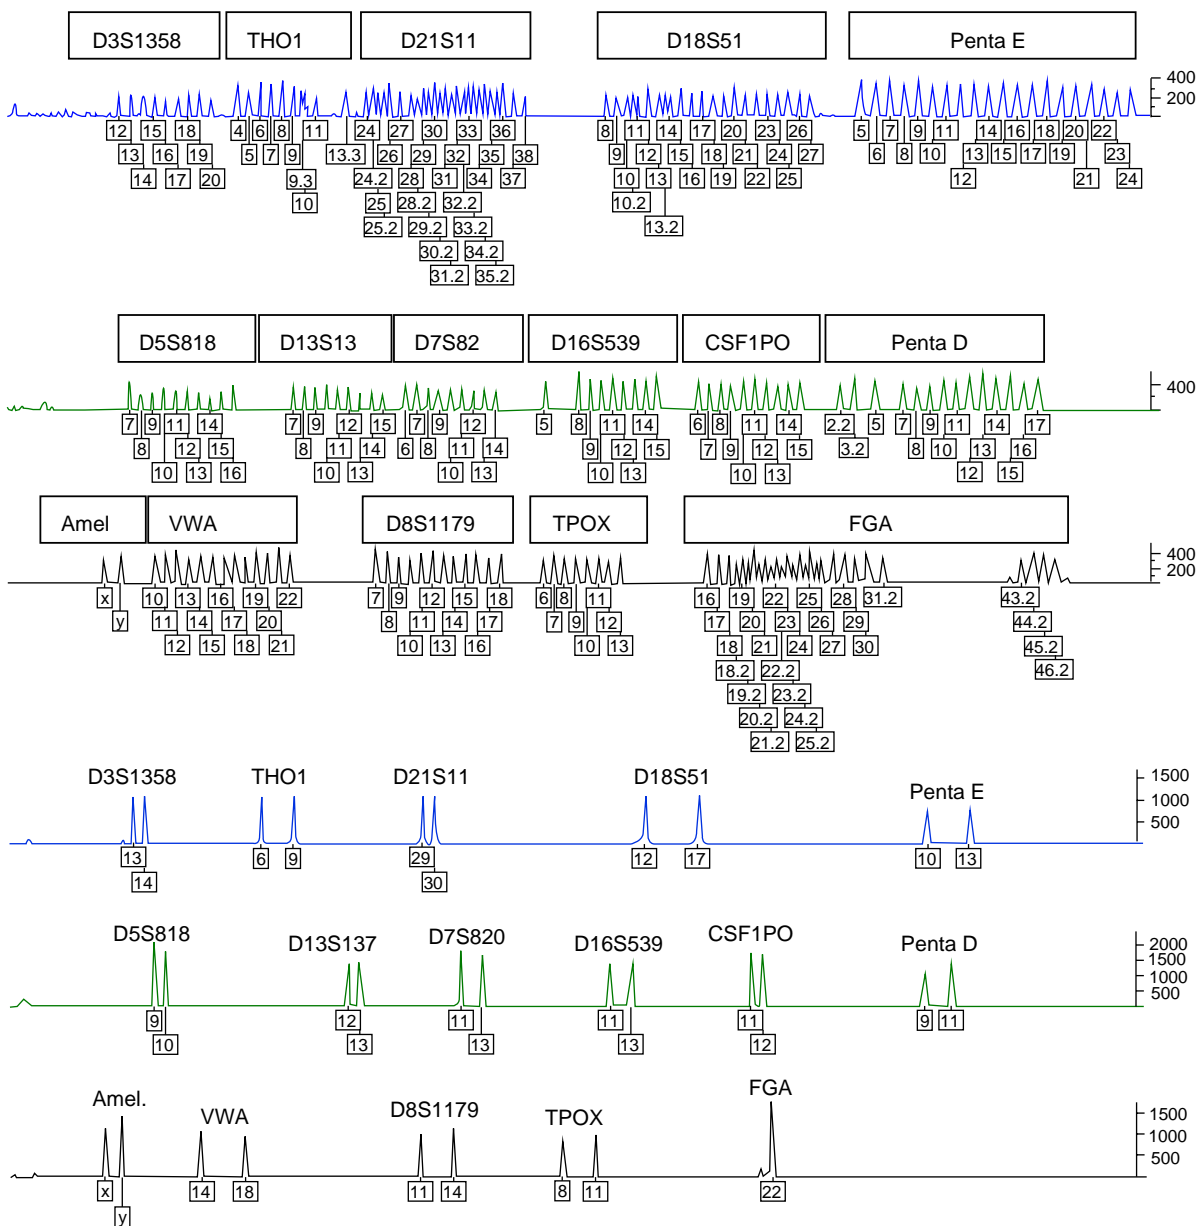

### Ultrasensitive Protocols

By performing enough cycles of PCR amplification, the theoretical sensitivity of any PCR technique is one molecule of target DNA. PCR analysis in forensic science is, however, not adjusted at this level of sensitivity. Indeed, disturbing artifacts dramatically affect the quality of the results when PCR is pushed toward its maximal sensitivity.

Despite these difficulties, ultrasensitive protocols have been designed that use more cycles of PCR amplification to try to retrieve information from even the tiniest traces encountered during the investigations. The key to these protocols is a sophisticated algorithm of interpretation of the results that takes into account the potential artifacts, e.g., the fact that some alleles of the source of the trace may not have been detected (allele drop out) or the fact that some alleles detected may be artifacts (spurious alleles). Such ultrasensitive protocols are also called low copy number (LCN) protocols. The interpretation algorithm relies on a Bayesian evaluation of the two competing hypotheses: the hypothesis of the accusation (the trace comes from the suspect), and the hypothesis of the defense (the trace comes from another unidentified person). This Bayesian estimation forces the laboratory to gather complex experimental data on the risk of allele dropout and the risk of spurious allele appearance with LCN protocols.

### Mitochondrial DNA

Virtually all the DNA of a cell is contained in its nucleus. However, cell compartments called

**Figure 3** Typical example of STR analysis results. The lower part presents the DNA profile of an individual's sample obtained using a multiplex STR analysis kit analyzing 16 markers. The individual analyzed is homozygous for STR FGA and heterozygous for all the other STRs. The upper part presents the DNA profile of a standard containing all the alleles frequently encountered in the population for the set of markers.

mitochondria contain their own small DNA: the mitochondrial DNA or mtDNA, a small 16 569-nucleotides-long DNA. Since mtDNA is present in multiple copies in each mitochondrion and each cell contains many mitochondria, mtDNA is present in thousands of copies per cells in contrast to the only two copies of nuclear DNA contained in the nucleus. For minuscule traces or degraded samples (e.g., hair shafts), mtDNA is thus logically the last chance target when the usual DNA profiling fails. Since

mtDNA does not contain repetitive sequences, the only polymorphisms available are sequence polymorphisms, which are clustered within a 1000-nucleotides long region called the control region. Using a technique called sequencing, the sequence of this control region can be revealed. Since two unrelated individuals display on an average eight nucleotide differences in this region, mtDNA analysis is a useful tool to exclude innocent suspects. Its power of discrimination is, however, limited and it will never be

a means of identification. Moreover, because of its maternal mode of transmission, mtDNA is identical across a whole family tree along the maternal lines of transmission. Although this characteristic is a limitation for the power of discrimination, it allows comparisons to be made between individuals with very distant relationships. This has found some uses in historical or genealogical investigations, or in the identification of remains where close relatives were not available for comparison. A well-known example was the identification of the remains of the family of the Tsar Nicolas II killed in 1917, and identified by comparison with descendants of close relatives.

### Y-STR Analysis

There are STRs on the Y chromosome as well, the so-called Y-STRs. Because of the mode of inheritance of this chromosome, the alleles of the Y-STRs are transmitted unchanged from father to son and further along the paternal lines. Y-STR analysis has thus properties symmetrical to those of the mtDNA. Although its power of discrimination is higher compared to mtDNA, it is anyway much lower than standard multiplex STR analysis. The main usefulness of Y-STR analysis is its ability to provide a DNA profile from mixed stains containing male DNA as a minor component among a larger amount of female DNA. Using standard multiplex STR analysis, the minor male DNA will provide a detectable contribution to the DNA profile only when it represents more than 10% of the total DNA. However, a full Y-STR profile will be obtained even when the stain contains a 1000-fold excess of female DNA. This helps to solve cases where the aggressor is male and the victim female, like sexual assault cases. Like mtDNA analysis, Y-STR analysis has also found some uses in the identification of remains where close relatives were not available for comparison, or in historical or genealogical investigations. A well-known example was the evaluation of the claims that Thomas Jefferson, the third president of the United States, might have fathered the children of his slave Sally Hemings.

### Single Nucleotide Polymorphisms

SNPs have raised tremendous interest in medical research because some SNPs are the basis of the variations in the individuals' sensitivity to diseases or their variable reactions to drugs. Very efficient methods have been designed for high throughput analyses of SNPs. Most of these methods are covered by the name 'DNA chip' analysis or 'DNA microarray' analysis (Figure 4). Indeed, most of the methods allow the typing of large sets of SNPs to be made on

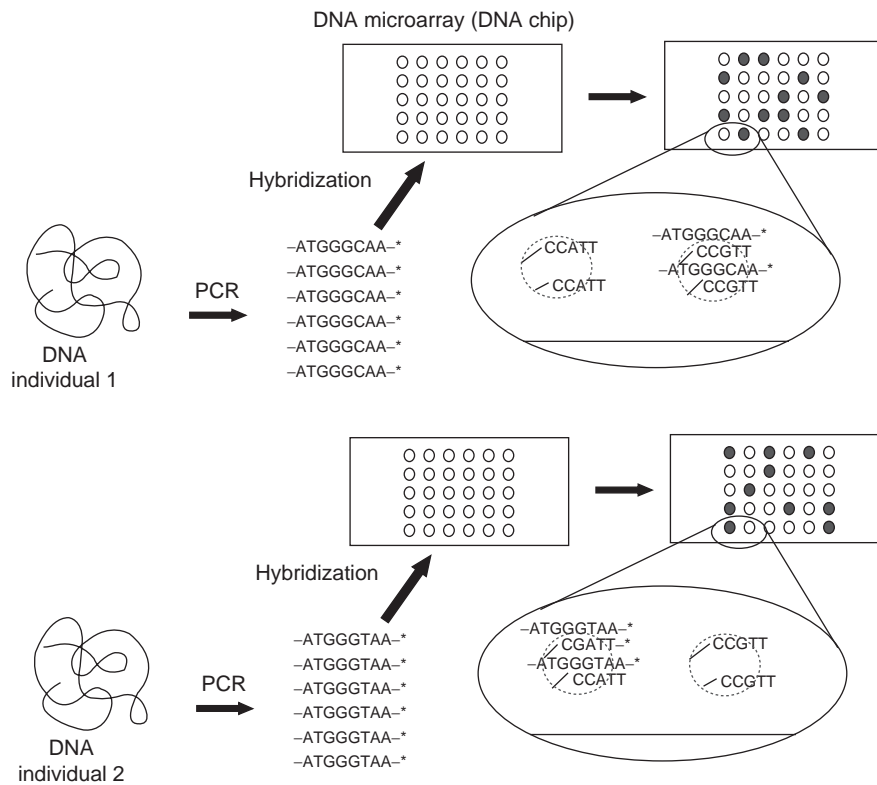

miniaturized devices resembling electronic chips. SNPs might become an interesting alternative to STRs as targets for forensic identification. Most SNPs usually have only two alleles and their power of discrimination is clearly much lower compared to STRs. But this weakness can easily be compensated by the use of a much larger set of SNPs. For a simple stain DNA analysis, a set of 50–100 SNPs is as powerful as a set of 10 STRs. For mixtures, however, the set of SNPs to be used should be much larger. But the technical advances may allow the analysis of thousands of SNPs to be made at a speed and at a price that is a fraction of that required for STR analysis. It is difficult to guess if SNP profiling will be able to replace STR analysis in the near future. However, SNP analysis will certainly be the method to gain morphological or ethnic information on the individual at the origin of a stain. DNA profiling is in essence a comparison process. It is of no use as long as a comparison sample is not available. However, it is clear that some of the morphological aspects of an individual are determined by his DNA. A stain could thus be submitted to a DNA analysis conceived to extract all these morphological informations (hair color, eye color, skin color, etc.). The genetic basis of these morphological polymorphisms are SNPs, whose details will certainly be better understood in the future. Morphology SNP kits will likely be designed to serve to focus the investigations toward the adequate subset of the population.

## Applications

### DNA Profiling in Practice

Any kind of biological material containing DNA may be used. The traditional types of traces can be easily analyzed: blood stains, semen stains, autopsy tissue, bone, etc. But thanks to the sensitivity made possible by the PCR, the largest number of samples submitted to DNA forensic laboratories is now saliva stains and above all contact traces (traces of the contact between skin and other surfaces). This is the main breakthrough of the last few years: the ability to make use of a large set of traces that were not even considered 10 years ago. The contact traces have led to the involvement of DNA profiling in the investigations of any type of crime, even the minor categories like burglary or theft that represent the largest category. As a consequence, the number of samples submitted to the DNA laboratory has exploded.

Although DNA profiling can make use of extremely faint traces, there are limits to its power. Logically, the traces have to contain the DNA of at least one cell. In practice, the requirements are higher. About

**Figure 4** Schematic description of SNP analysis on a DNA chip. The regions of the DNA harboring the SNPs are first amplified by PCR (only one SNP PCR product is displayed in the figure). The PCR is devised to obtain labeled and thus detectable DNA fragments. These are confronted to the set of DNA probes of the DNA chip and allowed to hybridize to their corresponding probes. The details of the hybridization are illustrated by zooming on the region of the DNA chip, which presents a pair of positions displaying the probes detecting two alternative alleles of an SNP.

a hundred cells are necessary to obtain a DNA profile using the standard methods. Since any human cell contains  $\sim 6$  pg of DNA, a trace has to contain  $\sim 0.5$  ng DNA for a successful DNA analysis. The requirements are naturally reduced for ultrasensitive LCN protocols. The DNA concentration is  $\sim 30$  ng DNA  $\mu\text{l}^{-1}$  in blood,  $400$  ng  $\mu\text{l}^{-1}$  in semen,  $2$  ng  $\mu\text{l}^{-1}$  in saliva, and  $0$ – $250$  ng per hair root. About  $0.01$   $\mu\text{l}$  of blood might thus be sufficient to provide a DNA profile. But such a small amount might be extremely hard to detect on a set of clothes and it is evident that some of the main difficulties of the forensic investigation of traces have shifted toward the detection of the minute traces of biological material theoretically exploitable. The availability of sensitive chemical or biochemical tests for blood and semen is sometimes of great help in this respect. For saliva, the available tests are less sensitive. For contact traces, there is no detection method. The sampling of the traces is done simply by assuming where the traces ought to be. A sometimes disturbing consequence is that the DNA profile obtained at the end of the analysis cannot be attributed to a specific material,

and the meaning of the presence of biological material from a suspect on a surface might be widely different if it is skin material or saliva.

An important factor in DNA profiling is the quality of the material. DNA is quite a robust molecule and usable DNA fragments have been recovered from 1000-year-old mummies. However, it can be very quickly degraded into smaller fragments when exposed to humidity, heat, or sunlight. Today's DNA-profiling methods target very short DNA fragments, the STRs. They may still be applied successfully on partially degraded samples. Furthermore, there are all the chemicals such as dyes or proteins contained in the traces or their support that can interfere in the delicate enzymatic steps involved in PCR amplification, the so-called inhibitors. All the DNA typing procedures involve a DNA isolation and purification step, which tries to eliminate the inhibitors. But their complete elimination is never warranted. Negative results (absence of DNA profile at the end of the analysis) then have to be critically scrutinized since they can be caused either by the absence of DNA or by the interference of inhibitors.

The remarkable sensitivity of multiplex PCR analysis of STRs makes it particularly vulnerable to contamination events. Accidental DNA exchange from one sample to the other, from lab personnel to the samples, etc., can occur and be unnoticed. The large-scale use of negative controls should reveal such contamination events. Moreover, the establishment of adequate laboratory design and use of pertinent working guidelines and decontamination procedures should prevent the occurrence of such damaging episodes.

Involuntary transfer of biological material is the cause of the existence of crime scene traces whose analysis has made a DNA-profiling techniques success. But involuntary transfer of biological material is also a matter of concern when it leads to contamination. In the worst scenarios, involuntary transfer of biological material can have even more worrying consequences when innocent sources leave traces that might be wrongly considered as crime scene traces. In such cases the power of DNA profiling may lead to the use of nonpertinent traces to accuse innocent persons of having a link to a crime. This danger is made even more likely by the extension of intelligence databases.

### DNA Databases

The identification power of DNA profiling makes the establishment of databases for the storage of DNA profiles not only possible but also highly desirable. DNA profiles from new or unsolved cases can be compared with the DNA profiles of the individuals stored in the database or can be compared between them with the hope of obtaining useful links. The standardization necessary for such purposes is a goal that has been reached at the end of the 1990s.

Almost all the industrialized countries have created a national DNA database for intelligence purposes. Depending upon the age of the database, and the legal framework limiting its use, between 0.1% and 2% of the population is usually on file. When the size of the database increases, the success rate reaches impressive level. For the largest databases available, the source of a crime scene trace is revealed by the database in more than 50% of the cases. The trend in most countries is then to adjust the limits of the database so as to include all the individuals ever convicted of a crime. It can be predicted that the DNA profiles of more than 10 million persons will be stored in DNA intelligence databases worldwide by 2010.

When such huge databases become connected, the occurrence of adventitious hits is no more an improbable possibility and becomes a real risk, even

with random match probabilities as low as  $10^{-15}$ . As a consequence, the number of markers analyzed might have to be increased.

### Interpretation

The power of the DNA evidence has to be evaluated by comparing two competing hypotheses. According to the Bayesian framework of evidence interpretation, it is usually expressed as a ratio of the probability of the evidence under the hypothesis that the evidential material has the same source as the comparison sample (the hypothesis favored by the accusation) and the probability of the evidence under the hypothesis that somebody else is the source of the evidence (the hypothesis favored by the defense). This likelihood ratio forms one of the core elements of the Bayesian framework of evidence interpretation. When the ratio is greater than 1, it supports the accusation hypothesis, and when it is lower than 1, it supports the defense hypothesis. In simple cases this ratio is inversely proportional to the frequency of the detected genetic characteristics in the adequate reference population. It is as much higher as the characteristics are rare.

The frequency of a DNA profile is calculated by multiplying the frequency of the result obtained at each STR analyzed. The frequency of the heterozygous genotype  $A_1A_2$  at a putative STR A is the product  $2a_1a_2$  (with  $a_1$  and  $a_2$  being the respective allele frequencies). For the homozygous genotype  $B_1B_1$  at STR B, the frequency would be  $(b_1)^2$ . The frequency of the combined genotypes is then  $2a_1a_2 \times (b_1)^2$  and so on for the whole profile. However, all these multiplications can only be done under the assumption of statistical independence between the events whose frequencies are multiplied. This translates into certain assumptions related to the genetic independence of the analyzed STRs and to the genetic homogeneity of the populations (Hardy-Weinberg equilibrium). The accumulated data demonstrate no major contradiction to the independence assumptions. Nevertheless, they show that real human communities do not behave like the ideal groups of population genetics, which are infinitely large, mate at random, and do not segregate. As a consequence, for improved accuracy, the frequency calculation of DNA profiles should include some correction parameters to take into account the imperfections of the real world. More important than the subtleties of population genetics is the dealing with situations where relatives of the suspects might also be potential suspects or situations where the suspect was identified through a database search. It is easy to get a gross overestimation of the power of the

evidence when these elements are not properly taken into account.

Further challenges in the interpretation process are encountered in cases of DNA profiles from complex mixtures of two or more DNA, and naturally with the DNA profiles obtained with the already mentioned ultrasensitive LCN protocols. In such cases, the Bayesian mode of interpretation displays its wonderful capacity to bring complex data into a coherent conceptual framework leading to sound and founded conclusions.

### Paternity Testing

The identification power of DNA profiling has naturally been used in paternity testing. Since a child has to share an allele with his biological father at each STR analyzed, the same multiplex STR kits, which serve so well the forensic science, can also provide powerful answers in paternity testing. But here, the question relates to the transmission of genetic material from one generation to the other. Then mutations have to be taken into account, which can cause apparent exclusions of true fathers for one or more of the STRs analyzed. The polymorphism of the STRs is linked to quite a high mutation rate (0.001–0.005 mutations per generation). These rates are high enough to bring an apparent exclusion of

the true father for at least one STR in every 50 cases of paternity testing. The statistical evaluation of paternity cases has to integrate these mutation rates. But the power of the DNA profiles is high enough to provide clear statistical evidence even with an apparent mutation at one STR of the multiplex set analyzed.

## Drug Screening in Sport

**L Rivier**, Laurent Rivier Science Consulting, Lausanne, Switzerland

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

In sports, sophisticated pharmacological products and methods have been used over the recent years. Besides stimulants and narcotics, anabolic agents and peptide hormones, many substances are used and abused to improve the mental and/or physical performance of athletes. This is called doping and contradicts both sport and medical ethics. The credibility of the excellence of performance and unpredictability of the outcome of a competition attract much enthusiasm from the public. If drug misuse or pharmacological manipulations of the athletes remove that unpredictability, the public will lose its interest in the outcome of these sports. Sports practitioners are basically healthy and should not be administered

pharmacologically active substances for any sound medical purposes. For the International Olympic Committee (IOC, [www.olympic.org](http://www.olympic.org)), the International Sport Federations, and the World Anti-Doping Agency (WADA, [www.wada-ama.org](http://www.wada-ama.org)), doping is considered as cheating. Such offence can be sanctioned by penalties as high as several years of suspension. The sports authorities take these important decisions after the laboratory has reported an adverse finding, i.e., the presence of a forbidden substance or its metabolite(s) in the athlete's sample (usually urine) at any concentration.

### The Compounds to be Screened

Because of greater concerns about the health of the young athletes (especially of adolescents, both male and female) and because of the obscure origin of the products as well as of the very high doses used, there is urgent need to implement the best screening capacity of the analytical procedures. Thus, all IOC

evidence when these elements are not properly taken into account.

Further challenges in the interpretation process are encountered in cases of DNA profiles from complex mixtures of two or more DNA, and naturally with the DNA profiles obtained with the already mentioned ultrasensitive LCN protocols. In such cases, the Bayesian mode of interpretation displays its wonderful capacity to bring complex data into a coherent conceptual framework leading to sound and founded conclusions.

### Paternity Testing

### Introduction

In sports, sophisticated pharmacological products and methods have been used over the recent years. Besides stimulants and narcotics, anabolic agents and peptide hormones, many substances are used and abused to improve the mental and/or physical performance of athletes. This is called doping and contradicts both sport and medical ethics. The credibility of the excellence of performance and unpredictability of the outcome of a competition attract much enthusiasm from the public. If drug misuse or pharmacological manipulations of the athletes remove that unpredictability, the public will lose its interest in the outcome of these sports. Sports practitioners are basically healthy and should not be administered

pharmacologically active substances for any sound medical purposes. For the International Olympic Committee (IOC, [www.olympic.org](http://www.olympic.org)), the International Sport Federations, and the World Anti-Doping Agency (WADA, [www.wada-ama.org](http://www.wada-ama.org)), doping is considered as cheating. Such offence can be sanctioned by penalties as high as several years of suspension. The sports authorities take these important decisions after the laboratory has reported an adverse finding, i.e., the presence of a forbidden substance or its metabolite(s) in the athlete's sample (usually urine) at any concentration.

### The Compounds to be Screened

Because of greater concerns about the health of the young athletes (especially of adolescents, both male and female) and because of the obscure origin of the products as well as of the very high doses used, there is urgent need to implement the best screening capacity of the analytical procedures. Thus, all IOC

and WADA accredited laboratories are asked to systematically test for stimulants, narcotic analgesics, anabolic agents, diuretics, peptide hormones, and other pharmacological agents and/or methods aiming to alter performance in sport, the list of which is automatically made known and regularly updated on the WADA website pages.

The WADA list of prohibited substances and methods is covering the following items on January 1, 2004.

## I. Substances and Methods Prohibited in-Competition

### IA. Prohibited Substances

**S1. Stimulants** All stimulants are prohibited, including both their optical (D- and L-) isomers and other substances with similar chemical structure or similar pharmacological effects.

#### Remarks:

- A few substances should present a concentration higher than a defined threshold (e.g., cathine is prohibited when its concentration in urine is greater than  $5 \mu\text{g ml}^{-1}$ ; each of ephedrine and methylephedrine is prohibited when its concentration in urine is greater than  $10 \mu\text{g ml}^{-1}$ ).

**S2. Narcotics** Only the following narcotics are prohibited: buprenorphine, dextromoramide, diamorphine (heroin), hydromorphone, methadone, morphine, oxycodone, oxymorphone, pentazocine, and pethidine.

**S3. Cannabinoids** Cannabinoids (e.g., hashish and marijuana) are prohibited.

**S4. Anabolic agents** All anabolic agents are prohibited.

1. Anabolic Androgenic Steroids (AAS)
  - a. Exogenous\* AAS and their analogs#.
  - b. Endogenous\*\* AAS including but not limited to androstenediol, androstenedione, dehydroepiandrosterone (DHEA), dihydrotestosterone, testosterone and their analogs.
2. Other anabolic agents: clenbuterol, zeranol.

#### Remarks:

- 'Exogenous' refers to a substance that is not capable of being produced by the body naturally.
- \*\* 'Endogenous' refers to a substance that is capable of being produced by the body naturally.

- # An 'analog' is defined as 'a substance derived from the modification or alteration of the chemical structure of another substance while retaining a similar pharmacological effect.'

Where a prohibited substance (as listed above) is produced by the body naturally, a sample will be considered to contain such prohibited substance when the concentration of that substance or its metabolites or markers and/or any other relevant ratio(s) in the athlete's sample deviates from the range of values normally found in humans (that is 'not to be consistent with normal endogenous production').

**S5. Peptide hormones** The following substances are prohibited, including their mimetics\*, analogs#, and releasing factors:

1. erythropoietin (EPO);
2. growth hormone (hGH) and insulin-like growth factor (IGF-I);
3. chorionic gonadotrophin (hCG) prohibited in males only;
4. pituitary and synthetic gonadotrophins (luteinizing hormone, LH) prohibited in males only;
5. insulin; and
6. corticotrophins.

Unless the athlete can demonstrate that the concentration of any of these endogenous peptides was due to a physiological or pathological condition, a sample will be considered to contain such prohibited substance as for the endogenous anabolic agents.

The presence of analogs, mimetics, diagnostic marker(s), or releasing factors of a hormone listed above or of any other finding which indicate(s) that the substance detected is not the naturally present hormone, will be reported as an adverse analytical finding.

#### Remarks:

- A 'mimetic' is defined as a substance with pharmacological effect similar to that of another substance, regardless of the fact that it has a different chemical structure.
- # An 'analog' is defined as for the anabolic agents.

**S6. Beta-2 agonists** All beta-2 agonists including their D- and L-isomers are prohibited except that formoterol, salbutamol, salmeterol, and terbutaline are permitted by inhalation only to prevent and/or treat asthma and exercise-induced asthma/bronchoconstriction.

When the laboratory has reported a concentration of salbutamol (free plus glucuronide) greater than  $1000\text{ }\mu\text{g l}^{-1}$ , this will be considered as an adverse analytical finding unless the athlete proves that the abnormal result was the consequence of the therapeutic use of inhaled salbutamol.

**S7. Agents with anti-oestrogenic activity** Aromatase inhibitors, clomiphene, cyclofenil, and tamoxifen, are prohibited only in males.

**S8. Masking agents** Masking agents are prohibited. They are products that have the potential to impair the excretion of prohibited substances, to conceal their presence in urine or other samples used in doping control, or to change hematological parameters.

Masking agents include, but are not limited to, diuretics, epitestosterone, probenecid, and plasma expanders (e.g., dextran and hydroxyethyl starch).

**S9. Glucocorticosteroids** Glucocorticosteroids are prohibited when administered orally, rectally, or by intravenous or intramuscular administration. All other administration routes require a medical notification.

## IB. Prohibited Methods

**M1. Enhancement of oxygen transfer** The following items are prohibited.

1. Blood doping. Blood doping is the use of autologous, homologous or heterologous blood, or red blood cell products of any origin, other than for legitimate medical treatment.
2. The use of products that enhance the uptake, transport, or delivery of oxygen, e.g. erythropoietins, modified hemoglobin products, including, but not limited to, hemoglobin-based blood substitutes, microencapsulated hemoglobin products, perfluorochemicals, and efaproxiral (RSR13).

**M2. Pharmacological, chemical, and physical manipulation** Pharmacological, chemical, and physical manipulation is the use of substances and methods, including masking agents, which alter, attempt to alter, or may reasonably be expected to alter the integrity and validity of specimens collected in doping controls. These include, but are not limited to, catheterization, urine substitution, and/or tampering, inhibition of renal excretion and alterations of testosterone and epitestosterone concentrations.

**M3. Gene doping** Gene or cell doping is defined as the nontherapeutic use of genes, genetic elements, and/or cells that have the capacity to enhance athletic performance.

## II. Substances and Methods Prohibited Out-of-Competition

During training, athletes can also abuse prohibited substances. Then, only the so-called long-term acting performance enhancing compounds are targeted during screening. Thus, S1 (stimulants), S2 (narcotics), and S3 (cannabinoids) groups of prohibited substances are not checked in these samples collected outside competition's time.

## III. Substances Prohibited in Particular Sports

Quite understandably, special pharmaceuticals, mainly psychoactive substances, are forbidden 'in-competition only' in specific sports.

**P1. Alcohol** Ethanol is prohibited, only in a few selected sports (e.g., when driving an engine is necessary) at variable levels ranging from 0 to  $0.5\text{ g l}^{-1}$ .

**P2. Beta-Blockers** Unless otherwise specified, beta-blockers are prohibited in a selection of sports like: Aeronautic (FAI), Archery (FITA) (also prohibited out of competition), Automobile (FIA), Billiards (WCBS), Curling (WCF), Football (FIFA), Gymnastics (FIG), Motorcycling (FIM), Shooting (ISSF) (also prohibited out of competition), Skiing (FIS) ski jumping & free style, as well as snow board, etc.

## Dedicated Procedures in Special Laboratories

As doping accusations can have major economical, sportive, and personal consequences, the whole procedure shall be forensic, e.g., strictly controlled, secured, and verified. That is why only accredited laboratories are allowed to proceed with these official analyses.

In practice, when each sample enters the laboratory, it shall be first classified into in- or out-of competition testing, but, for simplification reasons, the same screening procedures are applied to all of them. The interpretation of the results is adapted accordingly when the analyses are finished. Consequently, the existence of the official list of prohibited substances means that urine or sometimes blood samples

have to be searched systematically for more than 250 analytes, often at the low microgram per liter levels.

The analytical procedures for the small (e.g., stimulants) and medium-sized molecules (e.g., derivatized steroids or glucocorticoids) are using high-resolution gas chromatography (HR-GC) with nitrogen-specific detection or liquid chromatography (LC) with diode array detection, combined gas chromatography–mass spectrometry (GC–MS) and combined LC–MS on the full scan mode or selected ion monitoring mode. For larger molecules such as the peptide hormones, immunoassays and electrophoretic separation are preferred.

Recent statistics from the 32 IOC accredited laboratories have shown that more than 150 000 samples are analyzed annually worldwide, out of which less than 2% are declared positive by them. Around 50% of all these adverse findings are anabolic agents related to testosterone (Figure 1).

In general, this strictly controlled procedure for screening in sport doping is complex and includes the following key elements.

**Chain of custody.** As far as chain of custody is concerned, it starts well before the vials are entering the laboratory's area with the proper collection and tampering-proof transportation of the samples. In the laboratory itself, complete knowledge of the follow-up of each sample is recorded. It ends with the correct interpretation and reporting of the results and the disposal of the samples.

**Validated analytical methodology.** Analytical methods are implemented only if they have been correctly validated. The general procedure for method validation is defined in the several ISO (International Standards Organisation) 17025 companion documents. The accumulation of a vast body of analytical data is most often necessary covering both intra- and interlaboratory variations. WADA is the ultimate body that allows the use of a newly

developed procedure as it was demonstrated recently for EPO in 2002.

**Quality assurance including ISO 17025 and WADA accreditation.** Both WADA and ISO (International Standards Organization) 17025 accreditations are aimed at bringing all laboratories to the same level of good practice. Due to these elevated requirements for quality, doping control laboratories have to use highly specific and selective approaches and have to cope with some degree of harmonization of their methods. Thus, if clear rules have been disclosed in certain restricted professional circles, they might become mandatory for all the laboratories through the new WADA accreditation process that will take place starting from 2004.

## Short History of Doping Testing in Sport and Actual General Approach

For their own credibility, it is evident that these highly specialized laboratories have to agree between them upon common analytical procedures and interpretation criteria for the confirmation of identity of the compounds of interest. This was developed over the years, starting in 1967 with the first official human doping controls taking place at the Olympic games. At that time, the IOC had banned the use of sympathetico-mimetic amines and other stimulants, narcotics, tranquillizers, and antidepressive substances of the IMAO type. No steroids were included, even with the introduction of the GC–NPD at the Munich Winter Games in 1972, until 1976 at the Montreal Olympic Games with the use of a radioimmunoassay. Beginning 1983, GC–MS was systematically used and, since then, doping control laboratories have used to their advantage any technical advance as soon as they were available to them.

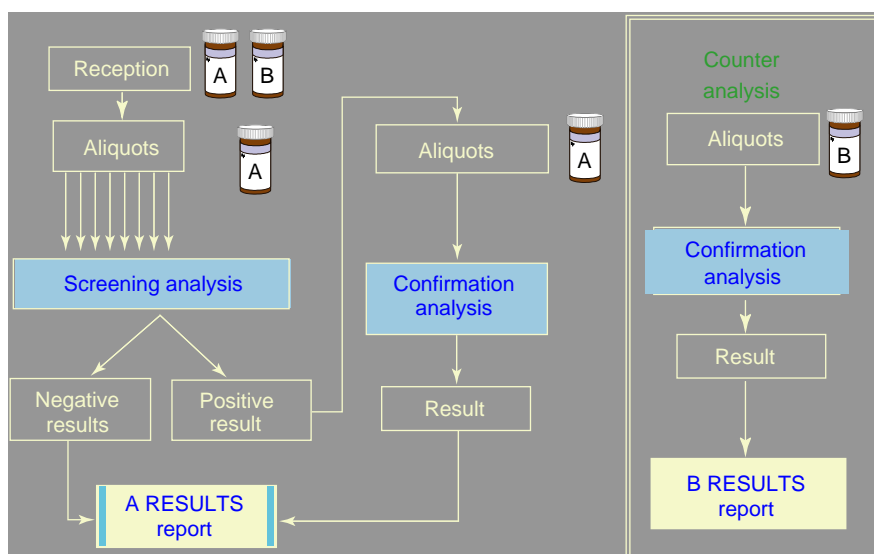

The most advanced analytical approaches are incorporated into doping controls. Today, MS and particularly GC–MS, is so far considered the less likely technique to be challenged in Court. Noticeably, LC–MS has significantly added to the extension of the panel of compounds already detected by GC–MS including large, polar, and/or thermolabile substances.

Now, the general strategy for handling and analyzing the samples within the laboratory is described in Figure 2.

After registering each sample, the volume and the aspect of the urine are recorded. The vial A is then opened and the pH and density are measured together. The analytical approach for the screening is presently restricted to the list of forbidden substances and the most important of their metabolites. It corresponds to approximately 200–250 compounds. Divided by

**Figure 1** Averaged distribution of adverse reports obtained on urine A samples emitted by all the IOC accredited laboratories in the recent years following the classes of prohibited substance. (Adapted from original 1995–2000 data released previously by IOC; see, for example, [www.olympic.org](http://www.olympic.org).)

**Figure 2** Place of the screening in the whole analytical process for doping controls. Positive samples are always confirmed before reporting an adverse finding. For safety reasons, sample B analysis – also called second confirmation or counter analysis – is performed on the athlete's and/or sport authorities' request almost always in the same laboratory as sample A.

groups of substances, the screenings for doping substances can be described as followed:

- Screening A. 5 ml: stimulants and volatile nitrogen-containing compounds – liquid–liquid extraction – GC-NPD analysis;
- Screening B. 5 ml: narcotic analgesics and  $\beta$ -blockers excreted free and/or conjugated – basic hydrolysis – liquid–liquid extraction, concentration – trimethylsilyl (TMS) derivatization – GC–MS full scan analysis;
- Screening C. 2 ml: anabolic steroids, some diuretics, some  $\beta$ -blockers and  $\beta$ -2-agonists – purification – enzymatic hydrolysis – extraction – concentration – TMS, trifluoroacetyl (TFA) derivatization – GC–MS selected ion monitoring (SIM) analysis;
- Screening D. 1 ml: diuretics and acids like THC-COOH – methylative extraction – purification – concentration – GC–MS full scan analysis;
- Screening E. 1 ml: peptide analysis for hCG, FSH, and LH – immunoassays; and
- Screening F. 1 ml: corticosteroids free and conjugated – extraction – LC–MS SIM and full scan analysis.

If specially requested by the sport authorities, separate urine aliquot is collected and screening for EPO and derivatives are done separately:

- Screening G. 20 ml: EPO analysis – ultrafiltration – gel electrophoresis – immunoblotting transfer – revelation and densitometry

This general approach is not permanent, but each time the laboratories improve the efficacy of the detection procedure, cheaters immediately turn into any possible remaining loopholes. As a recent example, tetrahydrogestrinone (THG), a new designer steroid produced specifically for the exclusive purpose to improve athletic performances, posed a real identification challenge to the laboratories. The development or the implementation of rapid, informative, and reliable systematic screening tests, which have the required sensitivity and can withstand the scrutiny of cross-examination at the Court, is constantly needed.

## The Specific Analytical Techniques Involved in Doping Controls

### Sample Preparation

In official doping controls, limited amount of urine (70 ml total) and blood (3–5 ml total) samples are available for the detection of all listed drugs including their metabolites.

The use of urine has been advocated as best sample for doping controls, in part due to the relative easiness of collection and in part because of the higher levels found in urine over blood. Most doping agents, especially steroids, are excreted with their hydroxyl function being substituted with either  $\beta$ -glucuronide or sulfate. Measurements of doping compounds excreted in urine are currently performed either as the

**Figure 3** The quantitative reaction for the derivatization of testosterone is obtained with a mixture of 50  $\mu\text{l}$  *N*-methyl-*N*-trimethylsilyltrifluoroacetamide (MSTFA)/trimethylsilyltrimethylsilane (TMSI)/dithioerythriol (DTE) (1000  $\mu\text{l}$ :5  $\mu\text{l}$ :5 mg) in a stopped vial at 60°C for 30 min.

free form or as their aglycone after hydrolysis of their conjugates.

The analytical criteria for reporting positive findings in screening are the following:

- At the minimum, the analysis should consist of two steps, namely, screening the A-sample and performing an A-sample confirmation.
- The order recommended for injection into the analytical instrument for confirmation analysis is: (1) reagent blank, if pertinent, (2) negative control urine, (3) sample being confirmed, (4) negative control urine, and (5) positive control urine.

At present, the most complex procedure for small and medium-sized molecules concerns the detection of all listed steroids at the low microgram per liter level in routine. It is presented here as a typical example:

- 5 ml urine;
- add 25  $\mu\text{l}$  methylandrostenediol ( $0.02 \text{ mg ml}^{-1}$ ) (Internal Standard);
- apply on  $\text{C}_{18}$  500 mg solid-phase extraction column (prewashed with 5 ml methanol and 5 ml  $\text{H}_2\text{O}$ );
- wash with 5 ml  $\text{H}_2\text{O}$ , elute with 3 ml methanol evaporate at 40°C with rotary vacuum evaporator add 1 ml phosphate buffer  $0.2 \text{ mol l}^{-1}$  pH 7.0, 30  $\mu\text{l}$  *Escherichia coli*  $\beta$ -glucuronidase (5000 units glucur);
- hydrolyze at 50°C for 1 h or at 37°C overnight cool at room temperature, then add 100 mg solid buffer; pH 8.5–9 (disodium carbonate: sodium hydrogen carbonate. 1:10 w/w) and 5 ml diethyl ether;
- shake 10 min, centrifuge 5 min, 2500 rpm;
- save organic phase (dried with sodium sulfate) evaporate to dryness, dry for at least 15 min in the vacuum chamber then add 50  $\mu\text{l}$  MSTFA/TMSI/DTE (1000  $\mu\text{l}$ :5  $\mu\text{l}$ :5  $\mu\text{l}$ ) warm at 60°C for 30 min; and
- inject 1  $\mu\text{l}$  to GC–MS

A key part of this procedure is the derivatization step that was optimized in order to give a single derivative of the target molecules with both sufficient thermal stability in GC and favorable fragmentation pattern in MS. This reaction is quantitatively silylating both hydroxy- and keto-groups for all steroids (Figure 3).

#### GC–MS Detection

Automated GC–MS instrumentation is best suited to run the many samples in a short period of time and to eliminate efficiently the many negatives. Quadrupole or ion trap MS instruments allow both automatic injection and treatment of the results. Printout of the results is obtained by running a series of specifically written macro commands. In general, total ion or selected ion traces are generally very complex even at restricted time windows, and targeted substances might be hidden behind the biological matrix background noise. A qualified laboratory technician will read the reports with a second person, usually a senior scientist, verifying the findings of the first. In any case, it is considered as a very tiring process where mistakes are most often occurring with possible false negative and one should not spend more than 60 min on it in a row.

Because of the so many true negative results (>95%) even at low microgram per liter concentration levels, the doping analyst should get best compromise between selectivity of the extraction and high recovery yield, speed, and low cost. As indicated in the steroids' procedure, liquid–liquid partitioning or solid-phase extraction – either manual or automated – are most commonly used. Immunoaffinity chromatography and LC fraction collection have recently been introduced for better removing the biological background most often seen in GC–MS detection. Together with GC–MS/MS, GC–HRMS has significantly improved the detection limit (Figure 4).

**Figure 4** On this illustration, the 'upper' trace shows that identification of 3'OH-stanozolol-*tris*-TMS ( $< 5 \mu\text{g/l}$  in a urine extract) by low resolution MS (upper window) had failed due to the high level of background. If the specificity of detection is enhanced ('middle': high resolution  $R = 10\,000$ , 'below': tandem MS), the limit of detection is essentially improved and the presence of the compound can be much clearly established. All other parameters (extraction, chromatography, ions detection) remained unchanged. Selected ion monitoring (SIM) traces for low nanogram level detection of one TMS derivative of the main Stanozolol metabolite found in urine. Upper part: recorded traces of  $m/z$  545.5 and 560.3 with a quadrupole MS running at the unit resolution; middle part: recorded traces of  $m/z$  545.3415 and 560.3650 with a high resolution MS; and lower part: recorded traces for transitions of  $m/z$  560.3 $\rightarrow$ 254.1 and 520.3 with a ion trap MS running at the unit resolution. Even if the resulting intensities of the ions – as indicated at the right hand side of the illustration – are lower, a higher selectivity provides a better signal to noise ratio. (Adapted from Kusamran T, de la Torre X, *et al.* (1999) Monitoring of low concentration anabolic steroids in urine samples by ion-trap GC/MS/MS. In: *Recent Advances in Doping Analysis*, vol. 7.)

On this illustration, the 'upper' trace shows that identification of 3'OH-stanozolol-*tris*-TMS ( $< 5 \mu\text{g l}^{-1}$  in a urine extract) by low-resolution MS (upper window) had failed due to the high level of background. If the specificity of detection is enhanced ('middle': high resolution  $R = 10\,000$ , 'below': tandem MS), the limit of detection is essentially improved and the presence of the compound can be much clearly established. All other parameters (extraction, chromatography, and ions detection) remained unchanged.

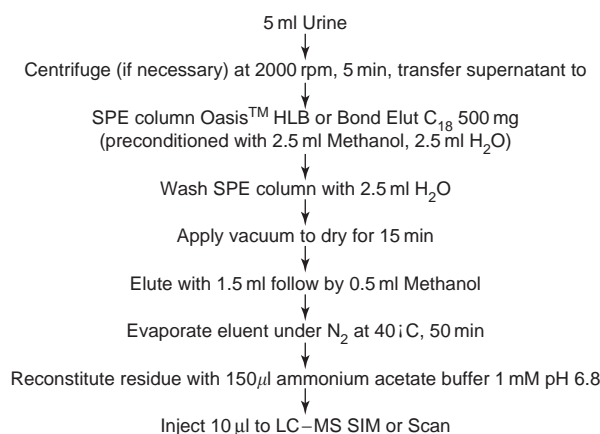

#### LC-MS Detection

The high polarity of the conjugates eliminated in urine limited the use of GC-MS or GC-MS/MS to the hydrolyzed samples only. Such measurements offer targeted molecules with modified structure for identification and rather imprecise quantitative measurements of each individual moiety. Recent advances in LC-MS interface technology have

allowed the detection of a larger pattern of thermolabile and polar compounds or metabolites involved in sport doping. One of the major advantages of liquid introduction in MS over other ways is that biological sample preparation can be greatly simplified. Sometimes, direct injection of the biological sample is even possible. For example, 11 abused corticosteroids can be rapidly extracted from 5 ml urine (Figure 5) and easily screened routinely in one single injection at the  $1\text{--}5 \mu\text{g l}^{-1}$  level by LC-electrospray ionization-MS (LC-ESI-MS). Many more applications of LC-MS can be expected in the near future.

#### Further Discrimination between Endogenous and Exogenous Doping Agents

Pharmaceutical testosterone and natural testosterone mass spectra are identical when measured with

**Figure 5** Extraction schema for LC-MS corticosteroids and confirmation. The procedure, that last ~2 h when automated with a suitable robotic system, can treat several samples in parallel.

ordinary MS detectors. In recent years, gas chromatography-carbon, online combustion-isotope ratio mass spectrometry (GC-C-IRMS) has been developed as a complementary technique to GC-MS. This technique made it possible to discriminate exogenous testosterone from endogenous testosterone by measuring  $^{13}\text{C}/^{12}\text{C}$  ratio of these steroids. Since the 1998 Olympic Winter Games in Nagano, GC-C-IRMS has been accepted in doping controls. However, a relatively large volume of urine (~25 ml) is necessary and time-consuming cleanup procedure is needed for obtaining the necessary highly purified steroid fractions. However, not all doping control laboratories are able to implement it on a routine basis.

## The Availability of Reference Dope Substances

Many doping substances are available at the requested purity for reference purpose through chemical factories. However, most of the metabolites are not. Consequently, all the laboratories are forced to prepare their own certified urines from controlled excretion studies. After the relevant permission from the medical ethical commission is granted, a small and unique dose of the doping agent is given to one volunteer. This healthy individual then delivers several urine samples that allow the laboratory to trace and identify the most relevant metabolites. After being analyzed, the remaining samples are mixed together. Several aliquots are then kept at low temperature until used as reference collection sample.

## Criteria for Identification

Practically, identification of a small molecule, based on its mass spectrum (MS) is usually obtained by passing the corresponding reference compound or standard the same day through the same analytical procedure and instrumentation, and then by comparing both the collected data. In this way, the laboratory will minimize instrumental variations to meet the required criteria for identification:

- Chromatographic separation
  - For capillary GC, retention time (Rt) or relative Rt (RRt) of the analyte shall not differ more than 1% from that of the same substance in the spiked urine sample, reference collection sample, or reference material analyzed in the same batch. In these cases where shifts in retention can be explained, for example, column overload, the Rt criteria can be relaxed. For LC, the Rt or RRt shall not differ more than 2%.
- MS detection
  - Full scan mode: all diagnostic ions with a relative abundance >10% in the reference MS obtained from a positive control urine or reference material analyzed in the same batch must be present in the MS of the unknown. In addition, the relative intensities of at least three diagnostic ions shall not differ more than the amount indicated in the Table 1.
  - If three diagnostic ions with relative abundance >10% are not available, a second derivative shall be prepared, or a second ionization or fragmentation technique shall be used. In any case, a minimum of two diagnostic ions is mandatory in each mass spectrum.
  - SIM mode: at least three diagnostic ions must be acquired. The  $s/n$  ratio must be >3. The relative intensities of any of the ions shall not differ more than the amount indicated in Table 1. For diagnostic ion with relative abundance <5% in the reference, the ion must be present in the unknown.
  - If the laboratory protocol requires three ions to be within a tolerance window to identify a substance, it is not permissible to collect additional ions and select those ion ratios that are within tolerance and ignore others that would not result in meeting identification criteria without valid explanation.
  - If three diagnostic ions are not available, a second derivative shall be prepared, or a second ionization or fragmentation technique shall be used. In any case, a minimum of two diagnostic ions is mandatory in each MS.
  - MS<sup>n</sup>: a minimum of three diagnostic ions must be monitored either as an MS or in the selected

**Table 1** Maximum tolerance windows for relative ion intensities to ensure appropriate uncertainty in identification (adapted from the WADA Laboratory International Standard)

Relative abundance (% of base peak)	EI-GC-MS	CI-GC-MS; GC-MS <sup>n</sup> ; LC-MS; LC-MS <sup>n</sup>
≥50%	± 10% (absolute)	± 15% (absolute)
<50 and ≥25%	± 20% (relative)	± 25% (relative)
<25%	± 5% (absolute)	± 10% (absolute)

Note: for example, absolute difference means 45–55% for a 50% ± (5% absolute) abundance. Relative difference means 40–60% for a 50% ± (20% relative) abundance.

reaction monitoring (SRM) mode. The *s/n* of the diagnostic ions must be greater than 3. The relative intensities of any of the ions shall not differ by more than the amount in Table 1 from the relative intensities of the same ions acquired in a spiked urine, reference collection sample, or reference material. For a diagnostic ion with a relative abundance > 5% in the reference, the ion must be present in the unknown.

## Analytical Approach for Large Molecules and Peptide Detection

These screenings are basically performed by immunoassays directly on the urine or blood, or after specific manipulation of the samples (e.g., ultrafiltration and concentration, blotting transfer, and electrophoretic separation). In principle, formal confirmation shall be obtained by using other immunological tests acting on a different epitope of the targeted molecule.

Today, if no hGH protocol is yet fully validated, an official test for recombinant EPO detection and its derivatives like Darbepoietine is in place since 1999. It is highly innovative and specific, but it is so sophisticated and time-consuming, expensive, and labor intensive that only highly trained technicians are able to perform it.

## Inter- and Intralaboratory Variations

Very few collaborative studies between accredited doping laboratories are available to determine their variances. As such determinations are rather complex, some of the experimental parameters are most of the time left uncontrolled. Great attention should be given to standardization of the methods. Matrix problems are known during calibration and best results can be obtained with the systematic use of good quality deuterium-labeled internal standards. The

sport authorities are fighting against the misuse of doping agents with the direct help of their accredited analytical laboratories, the efficacy of which is limited by the techniques used and the content's quality of the list of prohibited substances and methods.

The continuous implementation of new analytical techniques is mandatory to improve the deterrent effect of these controls. Regular interlaboratory comparisons should be organized to define more precisely the qualification level of each laboratory and to overcome the practical limitation of such methodologies. Better standardization of the analytical procedures and greater level in harmonization would probably add confidence to the results.

## Explosives

**R Sleeman and J F Carter**, Mass Spec Analytical Ltd., Bristol, UK

© 2005, Elsevier Ltd. All Rights Reserved.

This article is a revision of the previous-edition article by C R Midkiff Jr., pp. 1606–1612, © 1995, Elsevier Ltd.

### Introduction

In the forensic laboratory, explosives-related examinations are conducted to confirm the identity of a suspected explosive, to compare an explosive to one in the possession of a suspect, or to identify the material involved in an explosion. Explosives may be submitted for examination intact or as postexplosion debris. Intact explosives represent recovery of stolen explosives, undercover purchase, or a disarmed live or hoax device. Postblast samples are debris collected at the scene of a suspected accidental explosion or criminal bombing or following intentional detonation of an explosive device. In the examination of postblast debris, the analyst initially seeks to locate particles of the original explosive. When intact or partial particles are located, they are physically removed for testing free of interference from other materials in the debris. If no identifiable particulates are observed under low (10–30×) microscopic examination, residues characteristic of a particular class of explosive are sought. Residues may be combustion/decomposition products or residual traces of components of the original explosive such as nitroglycerin (NG) or nitrates used as the oxidizer.

### Types of Explosives Encountered

Most commonly encountered are low explosives or propellants that must be confined, as in a pipe, to be effective. Among inorganic propellant types is black gun-powder or a commercially modified black powder, Pyrodex. Organic propellants are primarily

smokeless powders; single-base, containing nitrocellulose (NC) only or double-base, containing NC and NG for extra energy and faster burning. Rarely, a low explosive of the commercial blasting agent type may be encountered, but because these require a primer charge for initiation, they are infrequent in criminal bombings. One widely used blasting agent is ammonium nitrate fuel oil (ANFO), ~95% ammonium nitrate and 5% fuel oil. A wide variety of improvised mixtures consisting of an organic fuel and an inorganic oxidizer is encountered, including such common materials as crushed match heads. Oxidizers typically comprise chlorates, perchlorates, or nitrates. Improvised devices may also contain fillers of pyrotechnic materials such as flash powders and flare compositions. Depending on formulation, certain flash powders may detonate and are classified as high explosives. Major components of several propellants or low explosives are shown in Table 1.

High explosives are those that detonate unconfined and are of commercial, military, and, rarely, improvised types. Typical examples of commercial high explosives are dynamite, water gels or emulsions, binaries, and certain plastic explosives such as Semtex or Detasheet. Military explosives are typically

**Table 1** Ingredients of representative propellants and low explosives

Explosives	Oxidizer	Fuel	Other

### Introduction

In the forensic laboratory, explosives-related examinations are conducted to confirm the identity of a suspected explosive, to compare an explosive to one in the possession of a suspect, or to identify the material involved in an explosion. Explosives may be submitted for examination intact or as postexplosion debris. Intact explosives represent recovery of stolen explosives, undercover purchase, or a disarmed live or hoax device. Postblast samples are debris collected at the scene of a suspected accidental explosion or criminal bombing or following intentional detonation of an explosive device. In the examination of postblast debris, the analyst initially seeks to locate particles of the original explosive. When intact or partial particles are located, they are physically removed for testing free of interference from other materials in the debris. If no identifiable particulates are observed under low (10–30×) microscopic examination, residues characteristic of a particular class of explosive are sought. Residues may be combustion/decomposition products or residual traces of components of the original explosive such as nitroglycerin (NG) or nitrates used as the oxidizer.

### Types of Explosives Encountered

Most commonly encountered are low explosives or propellants that must be confined, as in a pipe, to be effective. Among inorganic propellant types is black gun-powder or a commercially modified black powder, Pyrodex. Organic propellants are primarily

smokeless powders; single-base, containing nitrocellulose (NC) only or double-base, containing NC and NG for extra energy and faster burning. Rarely, a low explosive of the commercial blasting agent type may be encountered, but because these require a primer charge for initiation, they are infrequent in criminal bombings. One widely used blasting agent is ammonium nitrate fuel oil (ANFO), ~95% ammonium nitrate and 5% fuel oil. A wide variety of improvised mixtures consisting of an organic fuel and an inorganic oxidizer is encountered, including such common materials as crushed match heads. Oxidizers typically comprise chlorates, perchlorates, or nitrates. Improvised devices may also contain fillers of pyrotechnic materials such as flash powders and flare compositions. Depending on formulation, certain flash powders may detonate and are classified as high explosives. Major components of several propellants or low explosives are shown in Table 1.

High explosives are those that detonate unconfined and are of commercial, military, and, rarely, improvised types. Typical examples of commercial high explosives are dynamite, water gels or emulsions, binaries, and certain plastic explosives such as Semtex or Detasheet. Military explosives are typically

**Table 1** Ingredients of representative propellants and low explosives

Explosives	Oxidizer	Fuel	Other
Black gunpowder	KNO <sub>3</sub>	Charcoal/sulfur

trinitrotoluene (TNT) or cyclotrimethylenetrinitramine (RDX) and combinations of these. Easily improvised high explosives such as triacetone triperoxide are extremely shock sensitive and until recently have only infrequently been encountered in criminal activity. Other types of improvised high explosives have been used in terrorist bombings including mixtures of chlorate and nitrobenzene. Ingredients of some common high explosives are shown in Table 2.

## Analytical Methods for Low Explosives

### Physical and Chemical Tests

When an intact explosive material is available for examination, its morphology and appearance provide an initial guide to its identity. Black powder grains are usually pyramidal in shape with a shiny surface. Ignition of a single grain gives an instantaneous lavender flash for potassium nitrate (KNO<sub>3</sub>) or a yellow flash in the case of sodium nitrate (NaNO<sub>3</sub>). Pyrodex is a black powder propellant for firearms in which part of the KNO<sub>3</sub> is replaced with potassium perchlorate (KClO<sub>4</sub>). Two stabilizers are added to produce a powder of lower ignition sensitivity that reduces barrel corrosion. Grains of Pyrodex are roughly spherical and dark grey. Ignition is similar to black powder. Smokeless powder grains differ in morphology but intact particles are readily recognizable. Grains may be tubular, disk-shaped, spherical, flattened spheres, or flakes. Disk or tube grains may be perforated. On ignition, these burn smoothly rather than with a flash. Flash powder is typically a fine powder, silver in color, and loose powder burns with sparkles.

Smokeless powders are insoluble in water and are readily distinguished from black or flash powders, Pyrodex, or most improvised low explosives which have significant solubility. With inorganic explosives, qualitative analysis for identification may require only simple chemical spot, flame, or microcrystal

**Table 3** Chemical tests for inorganic low explosives

Anion	Chemical spot	Microcrystal
NO <sub>3</sub> <sup>-</sup>	Griess/Zn, Nitron, Brown Ring	Nitron (needles)

DPA, diphenylamine.

tests. A small amount of the suspected explosive is treated with hot water and filtered. Initially, the filtrate is tested for soluble oxidizer ions using the simple tests listed in Table 3. The results and information from Table 1 are used to begin characterizing the explosive material. The filter paper is dried and rinsed with pyridine to dissolve sulfur. The pyridine filtrate is collected and a few drops of 10% sodium hydroxide solution are added. A blue-green to brown color, depending on concentration, indicates sulfur. A residue on the filter, if black, is charcoal which can be identified by drying the filter paper and removing a small portion of the black residue. The residue is heated on the tip of a metal spatula until it glows. On removal from the flame, the charcoal will continue to

glow and slowly disappear, resembling the behavior of charcoal briquettes. If the residue is silvery, it is aluminum or magnesium, used in some pyrotechnic mixtures. These may be distinguished by treating separate portions of the residue on a microscope slide with dilute hydrochloric acid and sodium hydroxide and observing the reactions.

If desired, the approach above may be adapted to semiquantitative analysis of black powder, Pyrodex, or flash powders. A weighed sample, 0.25 g or more, on a tared filter paper is treated several times with a few milliliters of hot water, the filter dried, and the weight loss determined. The loss represents the oxidizer concentration. The filter is treated with pyridine, dried, and reweighed. The weight loss represents sulfur concentration and the residue either charcoal or aluminum as appropriate.

ANFO is typically yellowish spheres that dissolve slowly in water. Suspected ANFO is treated with a volatile solvent such as chloroform and the filtrate concentrated by slow evaporation for analysis by gas chromatography (GC) to identify the fuel oil component. The solid residue is dried and tested for ammonium nitrate by either chemical spot tests or instrumental methods. If weighed prior to solvent extraction, reweighing of the residual ammonium nitrate will demonstrate that the oil concentration is in the proper range for ANFO-type explosives.

Smokeless powders are characterized by morphology, physical dimensions, additives, and whether single- or double-base. To determine the base, a few grains of the powder are treated with acetone and the extract examined by thin-layer chromatography (TLC). A few milliliters are spotted on a silica gel plate and developed with a solvent such as 3:1 dichloroethane–carbon tetrachloride for ~10 cm. The plate is sprayed with ethanolic potassium hydroxide, heated at 100°C for 5–10 min, resprayed with Griess reagent, and reheated if needed. NC appears as a red spot at or close to the origin and NG, if present, at about  $R_F = 0.50$ . Alternatively, the grains may be extracted with methylene chloride and examined by GC. The use of GC–mass spectrometry (GC–MS) to distinguish single- and double-base powders has replaced TLC, in many laboratories, because of the unambiguous nature of the identification attained. If a few drops of acetone extract are added to water, a white film or threads of NC are observed. The identity of NC can be confirmed by infrared (IR) spectroscopy in preference to MS or GC–MS.

### Instrumental Analysis of Low Explosives

A variety of instrumental techniques is suitable for the characterization of low explosive propellants.

Scanning electron microscopy-energy dispersive X-ray analysis (SEM-EDX) provides a quick nondestructive determination of the elemental composition of the sample readily identifying barium, potassium, strontium, and chlorine. Inductively coupled plasma (ICP) emission spectroscopy or ICP-MS may be used to fully characterize the elemental composition of a material. X-ray powder diffraction (XRD) provides additional information. Data from the elemental profile are used in combination with a computer search of the powder diffraction file. In this way, compounds typical of a particular type of explosive can be identified, e.g.,  $\text{KNO}_3$  or  $\text{KClO}_4$ . Ion chromatography (IC) of a water extract detects soluble oxidizer cations and anions in an inorganic explosive, but for effective results, a very dilute solution must be used. Anions readily detected include nitrate, chlorate, and perchlorate. Cations such as potassium, sodium, and ammonium are also detected with excellent sensitivity. A complementary technique to IC, requiring an even smaller sample is capillary electrophoresis (CE), which has high sensitivity and short analysis time. For definitive identification of Pyrodex, liquid chromatography (LC) with ultraviolet (UV) detection is used to identify the characteristic additives sodium benzoate and dicyandiamide. Identification of NG may be made on an organic solvent extract by GC with either electrochemical or infrared chemiluminescence (also known as thermal energy analysis (TEA)) detection. GC–TEA systems are commercially available as ‘sniffer’ systems. Both LC and GC are also useful to identify additives or impurities such as dinitrotoluenes (DNTs) and stabilizers such as ethyl and methyl centralite or diphenylamine to characterize a sample by producer or brand.

### Identification of Residues Typical of Low Explosives

When postblast debris is received in the laboratory, visual examination may identify fragments of a potential container. Deflagrating explosives require a container such as a metal or plastic pipe or heavy cardboard tube to allow pressure to buildup. The presence of container fragments suggests low explosive use and examination of the fragments may provide additional information. In metal pipes, limited fragmentation suggests the use of a relatively low-energy filler such as black powder, Pyrodex, single-base smokeless powder, or an improvised mixture. Higher fragmentation and long thin strips of pipe suggest the use of double-base smokeless powder. With flash powder, residues such as silvery powder and bulking material, e.g., wood shavings, may

be found adhering to the inside surface of glue or epoxy sealed end plugs. A thin surface layer of silver grey aluminum may be seen on the inside surface of a cardboard tube. When sufficient residues are present, they may be removed from the surface manually or by rinsing with hot water. Surface aluminum may be difficult to remove but can be tested as described above directly on the surface. The hot water rinse is concentrated by slow evaporation to 1–2 ml and a few drops removed for anion testing using the spot or microcrystal tests described in **Table 3**.

For black powder, typical combustion/decomposition residues are: potassium sulfate ( $K_2SO_4$ ) and potassium nitrite ( $KNO_2$ ) (major), potassium carbonate ( $K_2CO_3$ ) or potassium hydrogen carbonate ( $KHCO_3$ ) and  $KNO_3$  (minor), and potassium thiocyanate ( $KSCN$ ) (trace). In some instances, an odor of hydrogen sulfide ( $H_2S$ ) may be noted when the test solution is acidified, indicative of sulfides, also seen as interference in the chloride test. Pyrodex produces similar products but a strong chloride test will be obtained and residual perchlorate may be detectable. To confirm Pyrodex as the filler, the extract should be tested for the two additives by LC. Burning of mixtures of black powder and chlorates may produce detectable levels of perchlorate but in tests of such mixtures, levels of residual chlorate are well in excess of those of perchlorate. Combustion of smokeless powders may produce significant levels of carbonates and some nitrites but, if no intact or partial grains are located, additional verification is needed, such as detection of NC/NG.

Both the original oxidizing anion and its decomposition products are often found in the case of improvised mixtures based on chlorates, perchlorates, or nitrates. One improvised explosive/incendiary is a mixture of sodium or calcium hypochlorite with a glycol. When this mixture is used, a strong odor of chlorine may be noted in the sample and chloride and hypochlorite are readily identified in a water extract. Another improvised mixture encountered in the UK is finely ground ammonium nitrate fertilizer and confectioner's sugar. The  $NH_4NO_3$  products are identifiable as described and LC is used for detection of the sugar. In residues from sugar-based improvised explosives, detection of 5-hydroxymethyl furfural by LC may be a useful indicator of the presence of sugar.

Cations are simply identified by acidifying the water extract of the sample with hydrochloric acid and conducting a flame test with a platinum wire loop. The lavender color of potassium is best observed through cobalt blue glass, which filters out the yellow sodium emission. High levels of strontium will also be seen through the cobalt glass but, because of its

intensity, the crimson is visible without the glass. A small spectroscope is useful for the observation of the characteristic spectral lines of barium or calcium if these are present. As indicated in **Table 3**, crystal tests are useful in confirming cation results but with the exception of ammonium ions are only rarely required.

When few or weak results are obtained with flame, spot, or crystal tests, IC or CE provides an excellent approach to the detection and/or confirmation of both anions and cations in residues from inorganic explosives. IC is especially valuable in the detection of carbonate, not easily identified by chemical tests, and thiocyanate, usually present only in very low amounts. Although it has been claimed that perchlorate is undetectable after an explosion, it is readily identified by IC. A major advantage of IC is that it detects a number of ions in a single run but because of its high sensitivity, the water used for extraction of the residue must be of high purity and handling procedures should avoid contamination from containers. In addition, the presence of ions detected at extremely low levels must be interpreted with care. As with the intact materials, SEM-EDX, ICP, and XRD provide useful information with XRD permitting identification of compounds characteristic of the particular explosive used.

When smokeless powder is suspected as having been used in a pipe bomb, the inside surface of the pipe is swabbed, rinsed, or, more effectively, the pipe fragments are sonicated with methylene chloride. The extract is filtered and concentrated by slow evaporation. The extract is examined by GC-TEA or LC-TEA or using an electrochemical detector to detect NG indicative of double-base powder. Similarly, GC-MS may be used for detection of NG with good sensitivity and excellent selectivity. The use of supercritical fluid extraction (SFE) has been used to extract smokeless powders and residues but the equipment cannot accommodate bulky fragments such as pipe fragments.

Pipe fragments may be extracted by sonication with acetone prior to TEA analysis. The concentrated acetone extract may be subjected to TLC as described above. Pipe samples without visible residue may be extracted with methylene chloride and examined by GC-TEA for the detection of NG. These pipe fragments may be re-extracted with acetone and the extract examined by TLC to detect the presence of both NG and NC. This provides good confirmation of smokeless powder as the explosive in the absence of even partial powder grains. Although examination of residues of low explosives by IR spectroscopy has been reported, the results are equivocal and difficult to interpret.

## Identification of Intact High Explosives

High explosives encountered in the forensic laboratory may be either pure or nearly pure compounds: nitro aromatics, nitrate esters, nitramines, or mixtures of these with or without other ingredients. A second category of high explosives with limited commercial application is the binary explosive. These involve the mixing of two, normally nonexplosive components, just prior to use to produce a cap-sensitive high explosive. A third, and more recent, type of high explosive is the gel or emulsion. This type, which is not normally sensitive to initiation by a number 8 detonator (a requirement for classification of an explosive as being cap-sensitive), incorporates one or more added sensitizers to permit initiation by a cap.

Aromatic nitro compounds, primarily 2,4,6-TNT, have long use as military explosives and commercial application in cast boosters to initiate insensitive blasting agents. In the laboratory, TNT maybe encountered as prills, flake, or a cast solid ranging in color from light yellow to brown. Acetone solutions of TNT slowly develop a pink color and red is produced with ethanolic KOH. Numerous TLC systems have been described for the identification of TNT, usually with visualization by alcoholic KOH. TLC or GC-MS identification of minor products, other isomers of TNT or DNT, provides information to establish a potential common source. The use of isotope ratio MS is now being explored for this purpose. GC or LC-TEA readily identifies TNT. Combinations of TNT and  $\text{NH}_4\text{NO}_3$ , known as 'Amatols', have been used as military explosives to conserve TNT and could be encountered in old military ordnance.

Nitrate esters such as NG and ethylene glycol dinitrate (EGDN) are the major explosive components of commercial dynamite. The reported 'nitroglycerin content' of dynamite represents a mixture of NG and EGDN, with EGDN being the major component. In some dynamites, only EGDN may be present. NG and EGDN are soluble in acetone and identifiable by TLC on silica gel or by GC with electron capture detection, GC-TEA or GC-MS. In recent 'nitroglycerin-free dynamites' the NG and EGDN have been replaced with nitro esters such as diethylene glycol dinitrate (DEGDN) or metriol trinitrate (MTN), which are identified using the same techniques. Other ingredients of dynamite that should be identified for characterization include  $\text{NH}_4\text{NO}_3$  or  $\text{NaNO}_3$ , which replace a portion of the 'NG', combustible fillers such as sawdust, walnut, or oat hulls on which the explosive oil is adsorbed, and

stabilizers such as calcium carbonate. A nitro ester commonly used as the filler in detonating cord and in sheet or plastic explosives such as Semtex is pentaerythritol tetranitrate (PETN). Pure PETN is a white powder identifiable by IR spectroscopy, TLC, or GC-MS. When examined by common 'dynamite systems' for TLC, PETN is poorly separated from NG and frequently exhibits streaking on the plate. During screening with a TLC system on silica gel, observation of significant streaking should be followed by reexamination on a 'PETN-specific' TLC system.

Cyclic nitramines such as RDX or cyclotetramethylenetetranitramine (HMX) are widely used in military composites such as Composition B (TNT and RDX) and Composition C-4 (US) or PE-4 (British) and in commercial blasting explosives such as Semtex (a Czech-made mining explosive). HMX is present as a by-product in RDX made by the Bachmann process and has applications in explosives to be used in high-temperature environments. Chemical tests for RDX include the 'J-Acid' and thymol tests. A number of TLC systems for RDX and HMX have been reported. With adequate sample, IR identification of the pure material in a micro-potassium bromide pellet is simple. If a diamond anvil sample holder or microscope attachment is available, excellent spectra of pure samples of milligram size or even of single crystals are easily obtained. When HMX is observed in RDX-based explosives, its concentration may suggest the national origin of the explosive.

Binary explosives are used primarily where only limited quantities are required or when a need for explosives cannot be anticipated. Because they are not considered as explosives until mixed, they can be safely stored and transported. A liquid-liquid type, PLX, was developed for minefield clearing and is composed of nitromethane sensitized with ethylene diamine. Commercial binary explosive products include Astrolite, based on hydrazine and  $\text{NH}_4\text{NO}_3$ . Astrolite was offered in both aluminized and non-aluminized formulations, the former advertised as the most powerful chemical explosive available. A more widely sold binary, Kinestik, combines finely pulverized  $\text{NH}_4\text{NO}_3$  and nitromethane. This combination, offered by several vendors, is the only binary explosive currently available commercially. To ensure complete migration of the liquid into the solid phase, a dye is added to the liquid. When the intact mixed explosive is examined, dye can be extracted from the solid with acetone, examined by TLC or GC-MS, and compared to the dye used by producers of the product. Identification of the  $\text{NH}_4\text{NO}_3$  is straightforward and nitromethane can be identified by low-temperature GC.

Among the newer commercial explosives are cap-sensitive water gel slurries and emulsions. For reasons of safety and economy, they are rapidly replacing dynamite in commercial practice and as a result of this wider availability, are increasingly being encountered in criminal activity. Although both are based on aqueous solutions of  $\text{NH}_4\text{NO}_3$ , in the water gel types a continuous phase of gel is produced with a polysaccharide such as guar gum, which serves both as fuel and gelling agent. Additional oxidizer or fuel, typically flake aluminum, may be dispersed in the gel to produce a slurry and most commercial products are, in fact, slurries. For improved storage stability or density control, co-oxidizers such as calcium nitrate ( $\text{Ca}(\text{NO}_3)_2$ ) may be used. To ensure cap sensitivity, voids or chemical sensitizers are added. The chemical sensitizers are generally nitrate salts of amines such as methylamine nitrate and hexamine nitrate with the sensitizer compound indicative of the producer. Voids used for sensitization are either entrained air or hollow glass microspheres  $<100\text{ }\mu\text{m}$  in diameter.

A suspected water gel is examined on a microscope slide to identify the microspheres used in slurry and emulsion explosives. The gel is directly extracted with methanol, which dissolves the amine salt, and a small amount of  $\text{NH}_4\text{NO}_3$ . TLC on a cellulose plate using a chloroform-methanol-water system separates the sensitizers. The plate is sprayed with ninhydrin and heated to visualize the amine salt. A second spray with diphenylamine in ethanol followed by long-wave UV irradiation visualizes the  $\text{NH}_4\text{NO}_3$  if desired. Alternatively, the methanol extract may be evaporated to near dryness, redissolved in water, and analyzed by IC to identify the sensitizer. An intact sample can also be extracted with water using either a small homogenizer or ultrasonic agitation to disrupt the gel structure. Microspheres float on the surface and are removed for examination by SEM-EDX to characterize the manufacturer. Spot tests and IC identify ammonium, calcium, and nitrate ions in the water extract. Flake aluminum, if present, is identified as described above.

Emulsions are extracted with pentane or hexane, which separates the emulsion and, after concentrating the solution, high-temperature GC is used to identify oil and wax. The residue from the organic extraction is dried and extracted with hot water to dissolve oxidizer(s). Testing of the water extract by spot tests or IC identifies ammonium, potassium, nitrate, and perchlorate ions when potassium perchlorate is used for increased sensitivity. Identification of the emulsifying system has potential for further characterization of emulsions. The residue from the water extract is primarily aluminum

granules, rather than the flake material used in gel/slurry types.

Improvised high explosives vary from the relatively simple to prepare but highly shock-sensitive-triacetone triperoxide or hexamethylene triperoxidediamine to obsolete explosives such as tetranitroaniline. In general, if an adequate collection of reference spectra is available, the pure material is probably best identified by IR spectroscopy as a micro-KBr pellet or by mass spectral techniques.

### Identification of High Explosives in Postblast Debris

Early work on detection of high explosives in debris samples focused on NG and EGDN from dynamite or gelignite-type explosives. Vapor headspace sampling using GC with electron capture detection is highly effective as are ion mobility spectrometry (IMS), GC-MS, or GC-MS/MS. Dynamite has also been identified by purge-and-trap collection on charcoal sorbent. With dynamite, particulates consisting of NC, binder material, adsorbed NG and EGDN, MTN, DEGDN, and ammonium or sodium nitrates often can be observed microscopically in the debris. Their removal permits identification of the components by GC-TEA, IR, GC-MS, LC-MS, TLC, IC, ICP, XRD, or chemical tests.

For plastic explosives, extraction of the debris with an organic solvent dissolves TNT, RDX, HMX, or PETN, which are then identifiable by TLC or a suitable instrumental method. Combinations of two or more high explosives and/or other ingredients such as oil, polyisobutylene, etc., suggest the original type of explosive.

Postblast identification of water gel/slurry explosives is usually based on detection of the characteristic sensitizer compound by swabbing of debris fragments with methanol or methanol-water extract. Purge-and-trap collection of ethylene glycol mononitrate has also been reported. TLC or LC of derivatives with UV absorption or photolysis and electrochemical detection are effective. IC of a water extract for cations may also be used to detect the amine salt. While considerable success has been obtained in postblast detection of water gel/slurry explosives, only limited work has been reported for the detection of emulsion explosives. Initial work indicates some success in postblast recovery of microspheres from detonation of emulsions. Because of their simplicity, and the common materials in their formulations, these explosives pose a significant challenge to postblast detection.

While not widely used, the binaries will similarly be difficult to characterize following an explosion.

An improvised chlorate–nitrobenzene binary explosive formerly used by terrorists in the UK was abandoned because its presence was suggested by the persistent odor of nitrobenzene (NB) both on the clothing of the handlers of the explosive and in the postblast debris. Relatively low levels of NB are easily detectable by vapor sampling and GC with electron capture detection. Commercial nitromethane (NM) binary types will probably exhibit little residual NM postblast, but container fragments may permit detection of the liquid absorbed into the plastic.

### Detection of Taggants

In the aftermath of the mid-air terrorist bombing over Lockerbie, Scotland, in 1988, in which 270 people were killed, it was recognized that the bomb detection equipment available at that time was inadequate. In terms of the trace detection of explosives, it was thought that the most common high explosives had vapor pressures that were so low as to preclude the realistic possibility of vapor detection. A range of more volatile ‘taggant’ materials was therefore proposed as additives to commercially available explosive formulations to ameliorate this situation. EGDN, *ortho*-, and *para*-mononitrotoluene (*o*-MNT and *p*-MNT) and 2,3-dimethyl-2,3-dinitrobutane (DMNB) were proposed as suitable contenders. These could be used both to enhance the detection of explosives prior to detonation and to trace explosive materials to their source postblast. In 1993, 34 countries ratified a convention recommended by the United Nations’ Council of the International Civil Aviation Organization (ICAO) requiring the marking of commercial explosives. This was to come into force in 1997, after which participating countries were given a grace period of 3 years in which unmarked stocks could be used up. There has been opposition to the use of such

taggants on a number of grounds, such as safety, environmental, and utility problems, as well as cost. It should also be recognized that an unknown proportion of terrorist bombings will involve commercially produced explosives. Neither the less taggants, in particular DMNB, are now widely incorporated into commercially produced explosives.

### Introduction

Fibers provide one of the most common and important type of trace evidence retrieved by crime scene

investigation. They are transferred from one surface to another in any case where contact between two individuals has occurred and have quite high evidential values to link the suspects to the crime scene. In the examination of fibers, there are two distinct areas: fiber identification and fiber comparison. The former gives information even when a suspect’s fiber is not available; when it is available, it is regarded a part of fiber comparison. The latter elucidates the identity of the suspect’s fiber and the fiber from known origin that is transferred and/or cross-transferred between each other at the crime scene. These

An improvised chlorate–nitrobenzene binary explosive formerly used by terrorists in the UK was abandoned because its presence was suggested by the persistent odor of nitrobenzene (NB) both on the clothing of the handlers of the explosive and in the postblast debris. Relatively low levels of NB are easily detectable by vapor sampling and GC with electron capture detection. Commercial nitromethane (NM) binary types will probably exhibit little residual NM postblast, but container fragments may permit detection of the liquid absorbed into the plastic.

### Detection of Taggants

In the aftermath of the mid-air terrorist bombing over Lockerbie, Scotland, in 1988, in which 270 people were killed, it was recognized that the bomb detection equipment available at that time was inadequate. In terms of the trace detection of explosives, it was thought that the most common high explosives had vapor pressures that were so low as to preclude the realistic possibility of vapor detection. A range of more volatile ‘taggant’ materials was therefore proposed as additives to commercially available explosive formulations to ameliorate this situation. EGDN, *ortho*-, and *para*-mononitrotoluene (*o*-MNT and *p*-MNT) and 2,3-dimethyl-2,3-dinitrobutane (DMNB) were proposed as suitable contenders. These could be used both to enhance the detection of explosives prior to detonation and to trace explosive materials to their source postblast. In 1993, 34 countries ratified a convention recommended by the United Nations’ Council of the International Civil Aviation Organization (ICAO) requiring the marking of commercial explosives. This was to come into force in 1997, after which participating countries were given a grace period of 3 years in which unmarked stocks could be used up. There has been opposition to the use of such

taggants on a number of grounds, such as safety, environmental, and utility problems, as well as cost. It should also be recognized that an unknown proportion of terrorist bombings will involve commercially produced explosives. Neither the less taggants, in particular DMNB, are now widely incorporated into commercially produced explosives.

### Introduction

Fibers provide one of the most common and important type of trace evidence retrieved by crime scene

investigation. They are transferred from one surface to another in any case where contact between two individuals has occurred and have quite high evidential values to link the suspects to the crime scene. In the examination of fibers, there are two distinct areas: fiber identification and fiber comparison. The former gives information even when a suspect’s fiber is not available; when it is available, it is regarded a part of fiber comparison. The latter elucidates the identity of the suspect’s fiber and the fiber from known origin that is transferred and/or cross-transferred between each other at the crime scene. These

examinations include several kinds of analyses such as morphological and fluorescence observation by several kinds of microscopes and investigation of optical and physical properties. Some instrumental analyses for color and fluorescence are evaluated by microspectrophotometer (MSP) and microspectrofluorimeter; inorganic elements in fibers are investigated by scanning electron microscopy with energy dispersive X-ray microanalysis (SEM-EDX); Fourier transform infrared spectrometry (FTIR)/microscopy and pyrolysis gas chromatography–mass spectrometry (Pyr-GC–MS) are widely utilized for the analysis of the polymer composition of man-made fibers.

## Fibers Encountered at the Scene of the Crime

Fibers encountered at the scene of the crime are retrieved directly or by using adhesive tapes from the surface of several kinds of materials such as clothes, floor, carpets, bed, and inside of a car. They are classified into two groups: natural fibers and man-made fibers. In natural fibers, there are animal fibers, from wool (sheep), goat hair (common goat, mohair, and cashmere), llama (Alpaca), camel, and rabbit hair, and various kinds of fibers obtained from other animals; they are frequently encountered in criminal laboratories. There also are vegetable fibers in this category. The most common is cotton, and others are hemp, linen, and jute. Another natural fiber is the mineral fiber asbestos. Man-made fibers may be subdivided into two groups: one is regenerated fiber, the other is synthetic fiber. In regenerated fibers, there are three generic classes: acetate, triacetate, and rayon. In synthetic fibers, the major generic classes are nylon, acrylic, and polyester, and there are various other generic classes, such as aramide, nitril, and olefin. Most of these generic classes have a number of subtypes, for example, common forms of nylon are nylon 6, nylon 6,6, and nylon 1,1. The classification of fibers and generic classes of man-made fibers is shown in Table 1.

## Fiber Recovery

Adhesive tape can be used to collect a sample of the surface debris from clothing or other surfaces. The tape is pressed onto a surface and then placed onto a clear plastic sheet. Debris from the sampled surface is thus collected and then securely packaged. A low-power microscope is used to locate fibers that are of interest. Such fibers can be removed by forceps from the tape lift and transferred to a microscope slide mounting for further examination. Some laboratories have adopted one-to-one, or 1:1, tape lifting. This

**Table 1** Classification of fibers

<i>Natural fiber</i>	<i>Man-made fibers</i>
<i>Vegetable fibers</i>	Acetate
Seed fibers	Acrylic
Cotton, kapok, etc.	Acrylonitrile
Bast fibers	Acrylonitrile/methylacrylate/ methyl vinyl pyridine
Flax, hemp, jute, ramie, etc.	Acrylonitrile/vinyl acetate

	Poly(vinylidene chloride)
	Triacetate
	Vinyl

consists of taking single tape lifts from each part of the entire surface area of a suspected contact. The positions are recorded so that there is a one-to-one mapping of the surface area. This has the advantage of preserving precise information of the place where recovered fibers were positioned, a more rigorous sampling of the surface debris, and ensuring that the tapes are not overloaded and causing difficulties in the searching and recovery steps in the fiber examination process.

The disadvantage of the 1:1 tape lifting process of surface debris recovery is that a large number of tapes is generated. The searching of tape lifts is a protracted exercise demanding a great deal of examiner's time and slowing the entire examination process. A potential solution is the use of automated devices to screen tape lifts and search for certain specified target fiber types.

There have been five such devices described. They are the Foster and Freeman Fiber Finder Fx5 made by Foster and Freeman Ltd, the Fiber Finder and Maxcan devices made by Cox Analytical Systems of Sweden, the Q550ffi by Leica Vertrieb GmbH, and the Lucia Fiber Finder from Laboratory Imaging, Czech Republic. They all operate by scanning tapings carrying the fibers using a charge coupled device camera in the case of the Fiber Finder, the Q550ffi, and the Lucia fiber Finder and a Line Scanner in the case of the remaining two. Their operation is in two stages. First, a tape containing reference fibers is prepared and scanned. These reference fibers having been selected as a potential source of transferred fibers to be found among the tape lifts of the evidence. The color of the reference fibers is recorded and used as the matching criterion. The tapes containing the fibers to be searched are then scanned and the positions of those fibers matching the reference fibers are recorded. The operator can inspect images of the matching fibers to eliminate obvious mismatches based on their morphology.

In operation the devices are effective in the hands of an experienced operator but the preliminary step of scanning the reference fibers means that they are most efficiently used where a large number of tapes have to be searched for the same set of fibers. They would therefore seem ideally suited for use in conjunction with 1:1 taping. It seems likely that this is one area of fiber examinations that will continue to be developed.

## Identification of Types

There are two purposes in forensic fiber identification: one is the determination of fiber type, the other

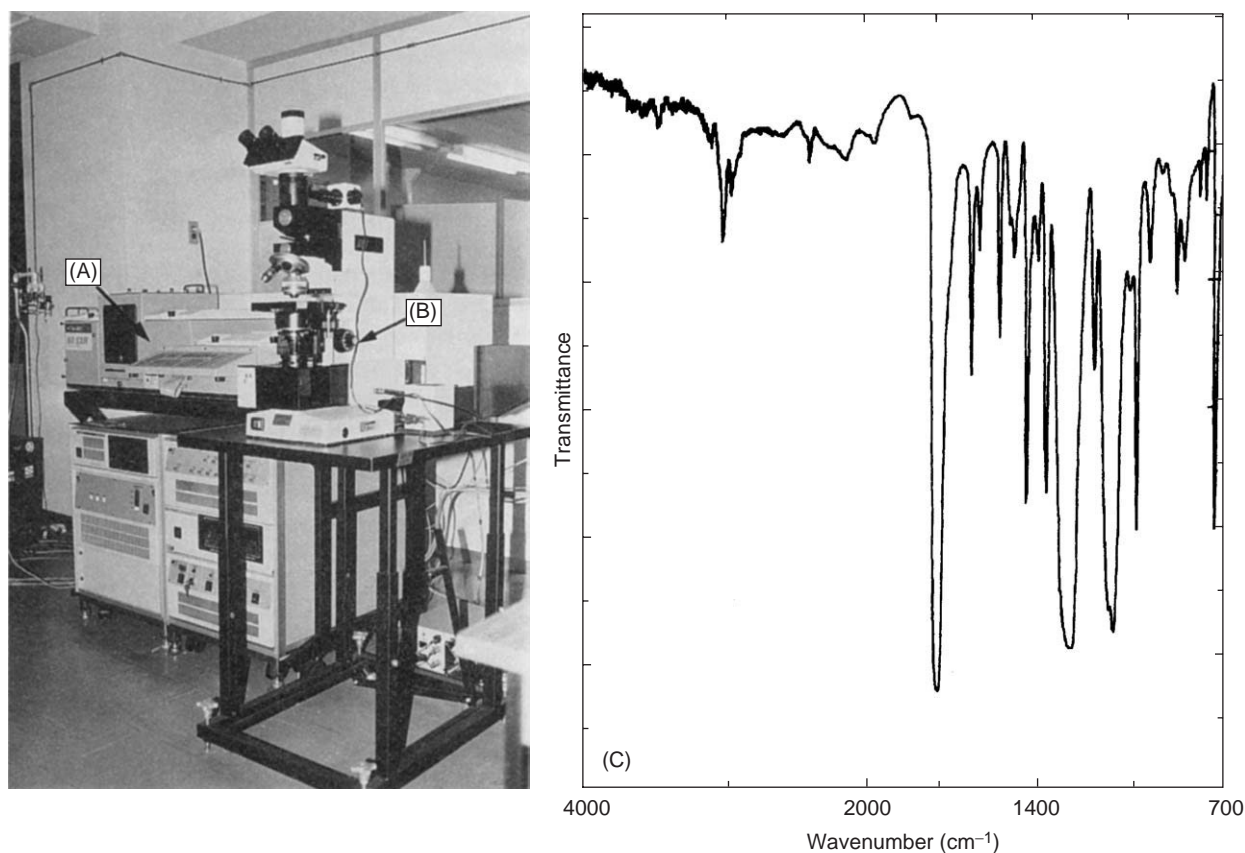

is determination of other characteristic properties of the fibers. In the first step of the fiber identification, a microscopic examination and investigation of optical properties are conducted. The microscopic appearance of the typical natural fibers cotton, hemp, wool, and silk are shown in **Figure 1**.

The diameter of the fibers, generic classes of natural fibers, the presence of delustrants and their distribution, birefringence, and refractive indices are also examined microscopically. Fluorescence and colors are measured by MSPs and microspectrofluorimeters under nondestructive conditions and color coordinates are calculated by an attached computer to evaluate the color objectively. In addition, if sufficient sample material is available, infrared (IR) spectroscopy (to clarify the polymer components), a staining test, hot stage microscopy for measuring melting points of fibers, and a solubility test for identifying generic classes may be carried out. But these tests, apart from IR spectrometry, are destructive and require large amounts of samples, so they are used only occasionally, and recently they have been replaced by other instrumental analyses. Furthermore, dyes used in fibers are identified, after their extraction from the fibers, by thin-layer chromatography (TLC) or liquid chromatography (LC).

In natural fiber identification for animal fibers, careful microscopic observation to assess the following components is important: one is the medulla, its structure, continuity, cuticular thickness, and the distribution and color of pigments; other important features are those of scales, such as its pattern, shape, margins, and changes. For vegetable fiber identification, polarizing microscopic analysis is also useful; for example, fibers that have a Z-type spiral are differentiated from those with S-type spirals.

**Figure 1** Scanning electron photomicrographs of (A) cotton, (B) hemp, (C) wool, (D) silk.

**Figure 2** (A) Fourier transform IR spectrometer with (B) Spectratech IR plan microscope attachment. (C) Infrared spectrum from a single polyester fiber measured by using the Spectratech IR plan microscope.

For synthetic fibers, identification only by microscopic observation and measurements of optical properties is insufficient. In addition to these examinations, analyses by FTIR/microscopy and Pyr-GC-MS are indispensable. The combination of FTIR spectrometry with a microscope makes it possible to measure IR spectra of a single fiber nondestructively and to identify the polymer subtypes, thus making this technique very valuable for fiber identification. An FTIR spectrometer with microscope attachment and the IR spectrum of a single fiber of polyester (polyethylene terephthalate (PET)) obtained by using this device are shown in **Figure 2**. Another application of FTIR microspectroscopy is to discriminate between fibers where chemical modifications have been used to give different properties. For example, acrylic fibers are defined as being composed of not less than 85% acrylonitrile polymer. The balance of the mass of the fiber can be composed of a copolymer used to enhance some attribute of the finished fiber for its end use. Acrylic fibers possessing less than 85% of acrylonitrile polymer are termed modacrylic fibers. Some examples of modacrylic fibers cannot be distinguished from acrylic fibers by microscopic examination (**Table 2**).

**Table 2** Acrylic fibers and variations

<i>Fiber type</i>	<i>Mass of acrylonitrile (%)</i>
Acrylic fiber	> 85
Modacrylic (BISFA definition)	50 > 85
Modacrylic (US definition)	35 < 85

Modacrylic fibers are composed of copolymers of acrylonitrile and a comonomer containing a halogen. The comonomer is usually either vinyl chloride ( $\text{CH}_2=\text{CHCl}$ ) or vinylidene chloride ( $\text{CH}_2=\text{CCl}_2$ ) but vinyl bromide and vinylidene bromide have also been reported to be used in fibers. The halogen groups give flame-retardant qualities to the fiber and the acrylonitrile components give thermal stability, light fastness, and strength. Also, other additives can be used to extend dyeability to different types of dye. The proportions of the monomer types can be varied by the manufacturer, even within the same trade name, according to the application intended for the fiber.

The presence of such additives and modifications can be detected in specimens of fiber fragments by making a detailed observation of the FTIR spectra. Such analyses can be important in forensic analyses

to determine the fiber type. Different formulations of the modacrylic can still carry the same trade name so that discrimination between fibers sold under the same trade name may be possible in some circumstances. The fiber environment is therefore a complex one, as illustrated by the modacrylics, because there are many additives and chemical modifications that may be used. In addition, many fibers that are no longer produced remain in use and are therefore potential sources of trace evidence.

## Dye Extraction and Analysis

For TLC and LC, dyes in fibers should be extracted by suitable solvents. It is possible to extract dyes from a single fiber. As an extracting solvent, a mixture of pyridine and water (4:3 by volume) is preferred for the majority of samples, but some modification may be required, and some dyes such as sulfur dyes on cotton are difficult to extract. A microcapillary glass tube is used to contain a single sample fiber; suitable extracting solvent is added, the tube is sealed at both ends, and is incubated usually at 100°C for a length of time dependent on the solvent and the dyes. The required minimum lengths of sample fiber for subsequent analysis by TLC or LC depends on many factors, such as the dyed fiber properties, the chemical class of the dyes, and the intensity of the colors. Extraction solvents and conditions for various fiber types are summarized in Table 3.

TLC is used for qualitative analysis; its reproducibility is relatively poor. For the analysis of dyes by TLC, extracts are spotted on areas as small as possible on the silica gel precoated plate and developed by a suitable developing solvent. Selection of developing systems depends on the chemical properties of

the dyes. Discrimination of the dyes is carried out by the comparison of  $R_F$  values of the components of the dyestuffs and the color of the separated spots on the plate, but such color comparisons are subjective. Extraction of dyes from the known fiber and suspect's fiber and their analysis by TLC should be conducted simultaneously under exactly the same conditions.

For LC, reversed-phase conditions are widely used for the separation of dyes, but in the case of basic dyes (cationic dyes used in acrylics), a silica column is utilized. Mobile phases also depend on the chemical properties of the dyes and ion-pair chromatography is widely used. Detection is achieved by measuring the absorbance in the visible region as well as at 254 nm. A photodiode array (PDA) detector makes possible simultaneous detection at several wavelengths and spectral analysis of the chromatographic peaks. If the absorption spectrum for the peak for each separated dye component is available, the color of the dyes can be assessed objectively and the combination of retention times and peak ratios obtained from the chromatogram; the spectral data make it possible to conduct an accurate and detailed comparison of the dyes.

## Color Matching

The color of fibers is one of the most significant characteristics in fiber comparison; color matching including fluorescence is inevitable for forensic fiber identification. Measurement of the color of fibers is conducted initially by microspectrophotometry. The MSP provides a great increase of discriminating power. Without this instrument, many false positive errors occur in fiber comparison. It is a convenient, nondestructive method that requires only a small amount of sample. Microspectrophotometry enables

**Table 3** Solvents and conditions for fiber dye extraction<sup>a</sup>

Fiber type	1	2	3	4
Cotton	Pyridine:water (4:3)	1.5% aq. NaOH	DMF:water (3:11)	DMF
Wool	Pyridine:water (4:3)	2% aq. oxalic acid (15 min at 90°C followed by pyridine: water (4:3))	1,2-Diaminoethane (90°C, 1 h)	
Acetate	Pyridine:water (4:3)	Methylene chloride		
Acrylic	Pyridine:water (4:3)	Formic acid:water (1:1)	Formic acid	DMF:water (3:1)

Triacetate	Pyridine:water (4:3)	Methyl propyl ketone		

<sup>a</sup>Extractions are conducted at 100°C in sealed tubes unless otherwise mentioned. Solvent ratios are by volume.

DMF=dimethyl formamide. (From Barry D and Gaudette BS (1988) The forensic aspects of textile fiber examination. *Forensic Science Handbook*, vol. 2, pp. 209–272.)

an evaluation of colors to be made objectively using UV-visible transmittance profiles. It is the 'only' technique available for comparison of colors when the sample fiber is too short or its color is too pale for TLC or LC. Furthermore, the attached computer can convert the color to numerical values of complementary chromaticity coordinates. Variations of the absorption spectra or complementary chromaticity coordinates are observed in the comparison of fibers, especially the natural fibers cotton and wool; the variation is due to the uneven uptake of dyes or the irregular cross-sectional shape of these fibers. It is essential, therefore, for forensic fiber comparison to conduct an adequate number of repeat measurements of control fibers to cover the range of variation on the absorption spectra or complementary chromaticity coordinates, and then to clarify whether the results of the measurement of suspect's fibers are within this range. The measured complementary chromaticity coordinates of control and suspect's fibers should be compared mathematically and statistically. An ellipse model for the variation of these complementary chromaticity coordinate values is proposed; the ellipse is larger for natural fibers, such as wool and cotton, than for man-made fibers. This arises from the greater variability in dye uptake.

The introduction of improved MSPs capable of reading down to 240 nm, in the UV spectral range, is enabling improved discrimination among indigo and black dyed fibers. A further development of the MSP instrumentation has been the introduction of PDA devices, which conduct scanning much faster than the older instruments. Indeed, the enhanced usefulness of MSP has led to the concept of a fiber examination workstation that employs a PDA mounted on a microscope incorporating both polarized light and fluorescence capabilities as well.

Blue and black denim clothing is one of the most common types of clothing. With so many potential sources of such fiber fragments their significance as evidence is often regarded as being too small to be useful. In studies using reference collections of identified fibers it has been demonstrated that UV-MSP is capable of resolving different groups within this category of fibers. Dyestuffs commonly used on cotton fibers are the reactive dyes, used for bright colors and which possess good color fastness, and sulfur dyes used for gray, brown, and olive-green colors. The reactive dye type is the most important class of dye used with cotton and its use is probably increasing because of environmental concerns over sulfur dyes. Other dye types include direct dyes, which can be used for many colors and are inexpensive but have poor color fastness, and the vat dyes. Vat dyes are often used for industrial applications due to their

resilience. Vat dyed fibers are usually dark blue-gray and sometimes yellow-gray.

The different dye classes can be determined by their spectra in most cases. The sulfur dyes are the most easily determined and the reactive dyes have characteristic spectra in the UV region, below 300 nm. It has been possible to identify several subgroups within the reactive dyes. The direct dyes and vat dyes produce spectra that can be readily distinguished from those of sulfur dyes and almost all of the reactive dyes.

A common type of cotton garment is blue denim clothing composed of indigo dye cotton textiles and the significance of the occurrence of indigo cotton fibers is considerably reduced due to the widespread prevalence of this material. However, in experimental comparisons of indigo dye and seven indigo derivatives, used on cotton fibers, a close examination of the spectra produced distinguished the eight different dyes by spectra produced from a single fiber specimen. Thus, even within blue dyed cotton fibers, usually regarded as a homogenous group, UV-MSP is a potentially discriminating measure. It is particularly significant that the dyes commonly used in cotton fibers used in denim textiles are reactive dyes. These dyes are less easily extracted by solvents and therefore less readily analyzed by dye separation techniques such as TLC. This further emphasizes the advantage of the nondestructive approach of microspectrophotometry.

If the sample amounts are adequate, dyestuffs may be compared by TLC or LC. The techniques, however, are destructive. For TLC of the dye components, the developing solvents depend on the chemical composition of the dyes. **Table 4** shows the TLC conditions recommended for separation of various dye classes.

Recently, LC techniques were introduced for the evaluation of dyestuffs. They have much higher sensitivity than TLC, the choice of conditions, mobile phase, and columns again depends on the chemical properties of the dyes, and an extraction procedure is also required. The results obtained by LC can be used for quantitative data processing and, by comparison of retention times, peak height or area ratios, and trace impurity detection by its higher sensitivity than TLC, more detailed discrimination of fiber samples is possible. Multi-wavelength detection using a PDA detector is also useful, as described above.

## Analysis for Metals

Metals analysis is usually conducted by SEM-EDX. Fibers sometimes contain inorganic elements as

tagging elements added by manufacturers to differentiate their product from others (see below). Metals from the dyes are also sometimes detected. For example, when the fiber, such as an amide fiber, wool, is dyed by acid mordant dyes, chromium is used in the coloration process and it is detected when this kind of fiber is analyzed. The results of energy dispersive X-ray microanalysis of wool fibers dyed by an acid dye and an acid-mordant dye are shown in Figure 3.

Other metals such as iron, copper, cobalt, and nickel are reported to be detected in metal-containing reactive dyes. In some cases, the fiber itself contains

several specific elements; for example, the presence of chlorine and bromine in modacrylic fibers can help to discriminate these fibers from the acrylic fibers.

## Additives and Contaminants

There are various types of additives in fiber samples. They are fiber dyes, fluorescent brighteners, delustrants, flammability retardants, and tagging metals.

There are about 10 000 dyes and pigments and they are used to produce characteristic colorations of fibers and textiles. They are divided into some generic classes and there is a wide range of colors in each generic class. These dyes are used as a single component or as a mixture; for example, black is produced by a mixture of yellow and blue components. The dyes are distinguished by class generic name and color index (CI) name. Color fibers are elucidated by MSP and dyes are also analyzed by TLC and LC for the purpose of fiber comparison by variety and complex composition of dye especially black dyes, as described above. Fluorescent brighteners are utilized to prevent fibers or textiles from bleaching even after allowed for a long period under sunlight irradiation. They absorb UV radiation from the sunlight and give off a blue fluorescence emission. Some of their main structures involve stilbene and coumarin.

Delustrants are added to some synthetic fibers (rayon, nylon, polyesters, and acrylics), which have a strong luster in order to control the opacity and luster. Titanium dioxide particles are widely used for this purpose; the delustrant properties are controlled by the concentration and particular size of the titanium dioxide. These particles can be observed microscopically and are useful for fiber comparison.

There are also some specialized fibers, such as flame-retardant fibers. They are utilized, for example, in hotel blankets, subway seats, and in aircraft. There are two methods of introducing flame retardancy. One is to blend in flame-retardant agents during the making of the fibers. Most flame-retardant agents are organophosphorus compounds. The other is to make inherently flame-retardant synthetic fibers. Some of these fibers are composed of poly(benzimidazole) and an aromatic copolyamide.

Trace amounts of inorganic elements, such as indium and samarium, are added to fibers by their manufacturers to distinguish their products from others; these elements are useful for forensic fiber comparison. The determination of these elements is carried out by SEM-EDX.

Contamination, which interferes in forensic fiber identification, is very frequent. Contaminants, such as blood and oil, interfere in the color evaluation of

fibers by microspectrophotometry; laundering also decreases the fluorescence properties of fibers and bleaching agents may cause false results. Oils and other organic substances also interfere in the measurement of IR spectra and change the chromatographic patterns obtained by Pyr-GC and cause the incorrect interpretation of the polymer composition.

## Other Methods

Microspectrofluorimetry is used to measure the fluorescence of fibers and to code it using the modification of the CIE (Commission International d'Eclairage) system. Fluorescence emission spectra are useful for the differentiation of fluorescent fibers. For excitation four spectral regions (UV, violet, blue, and green) are recommended for fiber comparison. The combination of Pyr-GC-MS makes it possible to obtain chromatographic and mass spectral data simultaneously. The Curie-point pyrolyzer enables the pyrolysis temperature of the fiber to be obtained in a very short time (200 ms) and this temperature is strictly controlled by the specific composition of the foil. For these reasons, high reproducibility of the pyrolysis of the fiber is obtained. Capillary gas chromatography is used for the separation of the volatile compounds produced by pyrolysis. The use of a computerized data processing system makes the analysis of the polymer components much easier and a detailed comparison of the components of man-made fibers is possible.

X-ray diffraction and X-ray fluorescence (XRF) spectrometry have been utilized in the differentiation of man-made fibers, but the sample amounts required are large, so that some modifications for single fiber analysis are required. Total reflection XRF has many advantages in this respect.

Though methods for identification of man-made fibers utilizing differential scanning calorimetry, differential thermal analysis, and thermogravimetric analysis have been reported, the sample amounts required are too large for actual case studies, so these methods are rarely used in forensic identification and are only adopted in very specific cases.

Another potential development in fiber analysis techniques has been the use of Raman spectroscopy for dye analysis. Electromagnetic radiation can interact with molecules so that it can be reflected, absorbed, or scattered. The light that is scattered can either be more energetic than the incident light, in which case it is called Stokes scattering, or of a lower energy, i.e., anti-Stokes scattering. This effect is called the Raman effect and is named after C.V. Raman, who was the first to observe this effect.

This type of spectroscopy offers a potentially highly discriminating and nondestructive method of analyzing fiber dyes. Its use has been curtailed by the lack of sensitivity that makes it unsuitable for application to recovered fiber fragments. However, certain refinements have been reported that offer the increased sensitivity required for this specialist application. These are resonance Raman scattering (RR) and surface enhanced Raman scattering (SERS). A further refinement is a combination of the RR and SERS developments, known as surface enhanced resonance Raman scattering. Studies using Raman spectroscopy have demonstrated the possibility of obtaining spectral information from dye pigments in polyacrylic and cellulose viscose fibers. The use of this approach for fiber dye analysis offers an alternative spectroscopic technique that can be applied to the fiber dyes *in situ* and so brings all the advantages of sequential testing using nondestructive techniques.

## The Significance of Fiber Evidence

The reporting of forensic fiber examinations has been contrasted with the numerical evaluations of the likelihood of a coincidental match commonly used for DNA analyses. One difficulty is that the total numbers of items of clothing that are being currently used and worn that possess any given fiber and dye combination are difficult to determine so that the 'population' of potential sources is unknown. Some workers therefore feel that the significance of fiber matches is consistently underestimated and as a result the overall value of fiber examinations has not been sufficiently recognized.

These impressions of underestimated significance are not supported by experimental evidence produced by exercises that set out to look for coincidental matches. In one such exercise the surface debris from a single evidence item from each of 20 different cases was compared. The cases were unconnected, except for their submission to the same forensic examiner, and the evidence items consisted of items of clothing. A total of 2083 fibers were collected from 20 evidence items and were compared using brightfield microscopy, polarized light microscopy, fluorescence microscopy, and MSP. Comparisons between fibers coming from the same garment that were indistinguishable were not counted and nor were colorless fibers and denim fibers. In the resulting comparisons no two fibers were found that could not be distinguished by the microscopy or analyses used.

The value of fiber examinations in forensic science in comparison to DNA analysis has been the subject

of comment and debate. An improvement in the instrumentation available, and its wider usage, is leading to greater discrimination potentials. The sheer complexity and diversity of the fiber environment poses a challenge to the statistical evaluation of fiber evidence but empirical studies of fiber frequencies consistently demonstrate that fiber matches can be highly significant, especially if more than one fiber type is involved. The speed of examinations, and hence cost-effectiveness, of fiber examinations can be greatly enhanced by the use of the improved instrumentation and its integration into the examination procedure.

## Introduction

Physical evidence at a crime scene may be present in an infinite variety of forms and materials. Some of the trace materials and marks left by the offender may be of limited evidential value, while others may be of significant benefit to the investigation. Several forms of evidence can permit the identification of an individual (e.g., fingermarks, dental structure, and

genetic code), but the patterns formed by the friction ridges of the fingers and palms are arguably the most useful and general proof of identity. These patterns are unique, immutable, universal, easy to classify, and leave marks on any smooth object handled with the bare hands.

Smooth objects that have been touched with the bare hands will retain latent impressions, composed of natural secretions and contaminants, of the corresponding ridge patterns on the fingers and palms. In criminal investigations, the detection and recording of a fingermark on a particular item can serve as proof that the item was touched by a specific person. It is for this reason that physical and chemical techniques, capable of developing latent fingermarks on

of comment and debate. An improvement in the instrumentation available, and its wider usage, is leading to greater discrimination potentials. The sheer complexity and diversity of the fiber environment poses a challenge to the statistical evaluation of fiber evidence but empirical studies of fiber frequencies consistently demonstrate that fiber matches can be highly significant, especially if more than one fiber type is involved. The speed of examinations, and hence cost-effectiveness, of fiber examinations can be greatly enhanced by the use of the improved instrumentation and its integration into the examination procedure.

## Introduction

Physical evidence at a crime scene may be present in an infinite variety of forms and materials. Some of the trace materials and marks left by the offender may be of limited evidential value, while others may be of significant benefit to the investigation. Several forms of evidence can permit the identification of an individual (e.g., fingermarks, dental structure, and

genetic code), but the patterns formed by the friction ridges of the fingers and palms are arguably the most useful and general proof of identity. These patterns are unique, immutable, universal, easy to classify, and leave marks on any smooth object handled with the bare hands.

Smooth objects that have been touched with the bare hands will retain latent impressions, composed of natural secretions and contaminants, of the corresponding ridge patterns on the fingers and palms. In criminal investigations, the detection and recording of a fingermark on a particular item can serve as proof that the item was touched by a specific person. It is for this reason that physical and chemical techniques, capable of developing latent fingermarks on

a wide variety of surfaces, are essential tools for the criminalist. Considerable research into these techniques has been conducted over the last 25 years, and this has led to a dramatic improvement in the sensitivity of fingerprint detection. Latent fingermarks that would once go undetected can now be exploited using routine processing methods.

The general term *lophoscopy* is used to describe the development, classification, and identification of the marks left by the papillary ridges of the skin. These friction ridges are only found on the inner surfaces of the hands (fingers and palms) and the soles of the feet. The study of fingerprints, or *dactylocopy*, forms the section of *lophoscopy* that is the most widely used in practice (even though marks from the palm of the hand or the sole of the foot may also be used for identification purposes).

The classification of fingerprints into distinct groups, based on general pattern similarities, allows the fingerprint examiner to limit the search for an unidentified fingermark to a specific section of the fingerprint reference collection. The various fingerprint classification systems in use throughout the world are based on three fundamental ridge formations: the arch, the loop, and the whorl (**Figure 1**). However, computer systems that entirely automate the storage, searching, and retrieval of fingerprints (automated fingerprint identification systems, or AFIS) have tended to render these traditional classification systems obsolete.

The individualization of fingerprints is achieved through the 'accidental' characteristics formed along the papillary ridges. These characteristics, or *minutiae*, may be summarized as three basic structures: the ridge ending, the bifurcation, and the dot (or island) (**Figure 1**). All other denominations, used for convenience or for statistical purposes, result from a

combination of these three ridge features. The study of friction ridge detail (ridgeology) may be further subdivided into the study of ridge contours (edgeoscopy) and pores (poroscopy). The majority of fingerprint identification experts, however, only exploit these latter subdivisions to a limited degree.

Two fingerprints may be considered to be from the same finger if a sufficient number of matching ridge characteristics is present and no unexplainable differences exist between the two prints. The actual number of minutiae required for a formal identification is, by tradition, somewhere between 8 and 18, with '12 points' being a common informal benchmark. However, there is no scientific basis for requiring a minimum number of matching ridge characteristics to reach a conclusion of identity.

## Latent Fingerprints

Three categories of fingermarks may be encountered as evidence at a crime scene or on an object collected for examination. Indented (or plastic) finger impressions are three-dimensional prints pressed into a malleable substance such as putty or candle wax. Visible fingermarks may be either negative, where the fingerprint ridges remove surface material such as dust or soot, or positive, where an image is formed by fingerprint ridges contaminated with a colored substance such as blood, ink, or paint. Latent marks are the most frequently encountered and cause the most difficulty for the criminalist; they are invisible and require treatment for their exploitation. The correct selection of a detection technique (or sequence of techniques) requires a detailed knowledge of natural secretions, together with a consideration of surface characteristics and environmental factors.

A latent fingermark, as deposited onto a surface by the friction ridges of the skin, is a complex mixture of natural secretions (**Table 1**) and contaminants picked up from the environment. Three types of glands are responsible for the natural secretions of the skin: the eccrine glands (found all over the body, but particularly numerous on the palms of the hands and soles of the feet), the apocrine glands (concentrated in the groin, in the arm pits, and in the perianal regions), and the sebaceous glands (principally located on the chest, the back, and the forehead). As the ridges of the hands are covered exclusively by eccrine glands, eccrine gland secretions are present to some degree in every latent fingermark at the moment of deposition. In addition, latent fingermarks often contain lipid material from the sebaceous glands due to contamination of the fingers from activities such as touching the face, combing the hair, etc. Apocrine gland

From Knowles AM (1978) Aspects of physicochemical methods for the detection of latent fingerprints. *Journal of Physics E: Scientific Instruments* 11: 713–721.

secretions are unlikely to be found in a latent fingerprint deposit except in particular cases such as sexual assault.

The latent fingerprint is invisible and hence, for its exploitation, it must be given characteristics that differentiate it from the surface on which it is found. This differentiation is normally achieved by inducing a coloration or luminescence in the mark by way of a physical or chemical treatment. In some cases, latent fingerprints may be detected using nondestructive optical techniques.

A good-quality latent fingerprint will generally contain ~1000 ng of material, sufficient for detection using a simple powdering technique. Chemical techniques such as ninhydrin treatment, which rely on the formation of a colored reaction product, will detect marks containing as little as 100 ng of material. Techniques that induce a strong luminescence (diazfluorenone (DFO), for example) have detection limits as low as 10 ng. When the quantity of natural secretions in the latent fingerprint falls below such levels, the developed print will tend to be weak and/or partial – generally unsuitable for identification purposes.

## Optical Detection Methods

### Inherent Luminescence

A small percentage of latent fingerprints exhibit a weak inherent luminescence that may be exploited for the detection of ridge detail. The luminescence is generally excited in the blue-green region of the

spectrum using a suitable high-intensity light source such as an argon ion laser or a filtered arc lamp. The origin of this luminescence is unclear but it is most probably the result of contamination of the fingerprint deposit rather than from natural secretions.

In some cases, the luminescence of the surface itself may be used to reveal fingerprint detail. For example, on smooth surfaces that are luminescent under ultraviolet (UV) light (as is the case with white glossy paper), observation under a UV lamp may reveal dark ridge detail against a light background. This is due to the absorption of UV light by the latent fingerprint deposit and the luminescence emission from the substrate.

### Ultraviolet Imaging

The optical detection of latent fingerprints by short-wave UV reflection requires the use of a UV-sensitive charge-coupled device (CCD) camera (equipped with a quartz lens) and a source of UV light. The technique is based on the contrast between the surface, which may absorb or reflect UV light, and the fingerprint deposit that absorbs some UV radiation and diffusely reflects the remainder. The technique may therefore give either light ridges on a dark background or dark ridges on a light background, depending on the nature of the surface and the composition of the fingerprint deposit. The type of UV lamp employed and the angle of incidence of the UV illumination are both critical factors for obtaining satisfactory results. A setup for the application of this technique is known as a reflected UV imaging system (RUVIS).

Another UV imaging technique involves the use of short-wave UV excitation (200–300 nm) with the observation and recording of the corresponding long-wave UV emission (300–400 nm). This form of UV emission has been observed with latent fingerprints on certain surfaces and with body fluids including blood, semen, and saliva.

### Diffuse Reflectance

This technique relies on the light being diffusely reflected by the fingerprint ridges. Latent fingerprints on glass, for example, can sometimes be revealed by varying the angle of incidence of the light source until an angle is found where the ridges diffusely reflect the light while the surface itself remains dark.

Episcopic coaxial illumination is a relatively simple optical setup that exploits diffuse reflectance for revealing fingerprints on smooth, shiny surfaces such as glass, plastic, and polished metal (e.g., firearms). A semitransparent mirror is employed to observe the reflection of white light perpendicular to the surface under examination. The light is diffused by the fingerprint

deposit but specularly reflected by the shiny surface. A dark image of the print will be observed against a light background. This method can also be very effective for the enhancement of fingermarks developed by cyanoacrylate fuming (see below).

## Fingerprint Detection on Nonporous Surfaces

### Powders

Powdering is the traditional fingerprint detection technique used by law enforcement agencies worldwide. Fingerprint powders may be readily applied at the crime scene on all nontransportable objects that have smooth, nonporous surfaces (e.g., gloss painted surfaces, glass, and metal). The powder particles adhere to the humid, sticky, or greasy substances in the latent fingerprint deposit. The technique is economical, relatively easy to apply, and the results are immediately apparent. An additional advantage is that a developed fingermark can be lifted off the surface using an adhesive film.

Many substances and formulations have been investigated as fingerprint powders (e.g., carbon black, graphite, metal oxides, sulfates, and carbonates), but the most sensitive powder for general use is considered to be aluminum flake. Aluminum flake powder, because of the flat plate-like structure of each particle and a surface layer of stearic acid, adheres particularly well to a latent fingerprint deposit. In addition, its hardness and reflectivity aid in the photography and transfer of developed prints.

Fingerprint powder is commonly applied to a surface using a brush, which may have bristles that are synthetic (e.g., fiberglass filaments) or natural (e.g., squirrel or camel hair). A developed fingermark may be subsequently lifted, using adhesive tape or gelatin film, and the lift transported to the laboratory.

Magnetic fingerprint powder, produced by mixing iron grit with aluminum flake, may be applied to a surface using a magnetic wand. This technique is less destructive than conventional powdering as there are no bristles coming into contact with the fragile fingerprint deposit. Colored or luminescent powders have been developed for special cases where conventional powder formulations give unsatisfactory results. A UV-luminescent powder, for example, may be useful for the detection of latent marks on a nonporous, multicolored surface.

Powdering is a physical process that is not particularly sensitive. As latent fingermarks age, they dry out, lose their stickiness, and become less receptive to fingerprint powders. This process will therefore detect only relatively fresh, good-quality latent

fingermarks. As a result, fingerprint powders are typically reserved for the treatment of large or fixed surfaces at the crime scene. More sensitive fingerprint detection methods are applied to objects that can be conveniently transported to the laboratory.

### Small Particle Reagent

Latent fingermarks may be detected on wet, nonporous surfaces by treatment with an aqueous suspension of an insoluble powder followed by rinsing with water. The small particle reagent (SPR), as it is commonly known, is typically prepared from powdered molybdenum disulfide and a detergent mixed with tap water. The powder suspension can be conveniently applied to the surface using a garden spray. As with conventional fingerprint powders, the molybdenum disulfide particles adhere to the greasy, water-insoluble components of the latent fingerprint deposit. The treated object is then rinsed with water to remove excess reagent.

As SPR is a wet powdering technique that is not particularly sensitive, it is reserved for the treatment of wet objects at the crime scene that cannot be readily transported to the laboratory for conventional processing. For example, it may be desirable to treat a wet stolen motor vehicle with SPR rather than wait for the car to be dried before processing by another method.

### Cyanoacrylate Fuming

Cyanoacrylate esters (generally the methyl or ethyl ester) are colorless, monomeric liquids sold commercially as quick-setting, high-strength adhesives (e.g., Superglue<sup>®</sup>). These esters polymerize rapidly at ambient temperature via an anionic mechanism in the presence of weak bases such as alcohol and water (Figure 2). The reaction product, polycyanoacrylate, is a hard white solid.

Cyanoacrylate vapor, formed by evaporating the adhesive at room temperature or by heating (80–120°C), selectively polymerizes on latent fingerprint ridges to form a solid white image of the fingermark. The moisture and alcohols present in the latent deposit catalyze the polymerization. Excellent fingerprint detail can be obtained on nonporous surfaces such as glass, metal and plastic, even with relatively old latent marks (up to several years of age).

Typically, objects to be treated are left in an enclosed chamber in the presence of a small quantity of cyanoacrylate ester that is generally heated to aid evaporation (Figure 3). The objects are removed when sufficient fingerprint detail is observed. More recently, vacuum cyanoacrylate systems have been developed that are purported to give better fingerprint detail within a shorter period of time.

**Figure 2** The polymerization reaction of cyanoacrylate ester in the presence of an anionic catalyst, leading to the formation of polycyanoacrylate, a hard white solid.

**Figure 3** Example of a commercially available cyanoacrylate fuming chamber.

Cyanoacrylate developed marks on smooth, flat surfaces such as credit cards may be efficiently recorded using diffuse reflectance (episcopic coaxial illumination) as described previously. In general, the contrast in cyanoacrylate-developed marks may be significantly enhanced by the application of a colored

or luminescent stain. The choice of a particular staining technique will depend on the color and the luminescence properties of the surface under examination. Examples of commonly employed staining procedures include gentian violet, rhodamine 6G, Ardrex<sup>®</sup>, Basic Yellow 40, and safranin.

Cyanoacrylate fuming may also be followed by vacuum metal deposition (VMD) in cases where background printing or background luminescence interferes with normal enhancement procedures (e.g., some credit cards, polymer banknotes, etc.).

### Vacuum Metal Deposition

Fingerprint contamination on a smooth, nonporous (or semiporous) surface can hinder the deposition of metallic films following metal evaporation under vacuum. This phenomenon has been known for a significant period of time but its application to fingerprint development is relatively recent. It is now accepted that VMD is one of the most sensitive techniques for the detection of latent fingerprints on surfaces such as glass and plastic.

A commercial VMD chamber is required for the treatment of articles by this method. After a vacuum is achieved, gold is first evaporated to form a very thin layer of metal on the surface under examination. A layer of zinc is then deposited in a similar manner. (Cadmium may also be used but this metal is generally avoided due to its toxicity.) The gold film is uniformly deposited across the surface of the sample and penetrates the latent fingerprint deposit. The zinc then deposits preferentially on the exposed gold but does not penetrate the fingerprint deposit. This results in transparent fingerprint ridges against a zinc-plated background. On some polymer substrates, depending on the amount of gold deposited, reverse development may also occur (i.e., zinc-plated ridges against a transparent background).

VMD processing can give excellent fingerprint detail on surfaces such as glass and plastic, even for very old or degraded marks. The technique may also develop fresh latent fingerprints (less than 48 h old) on fine-weave synthetic fabric. On some surfaces, such as polymer banknotes, there may be an advantage in using the sequence:

Cyanoacrylate fuming → VMD → Luminescent stain

## Fingerprint Detection on Porous Surfaces

### Ninhydrin and Ninhydrin Analogs

Ninhydrin is the most widely used chemical reagent for the detection of latent fingerprints on porous

surfaces such as paper and cardboard. The compound reacts with the amino acid (eccrine) component of the fingerprint deposit to give a dark purple product known as Ruhemann's purple (Figure 4). The chemical processes involved are quite complex and development conditions, such as temperature, acidity (pH), and humidity, must be controlled if optimum results are to be obtained.

Paper items are typically treated by brief immersion in a nonaqueous solution of ninhydrin. (For example, ninhydrin may be dissolved in a limited quantity of polar solvent and acetic acid, and then made up to volume with a nonpolar carrier solvent such as HFE-7100 or HFC-4310. A final concentration of ~0.5% w/v is usually employed.) The solution may also be applied using a brush or spray. After drying, fingerprint development is generally achieved at room temperature over 24–48 h, with 50–80% relative humidity being required for optimal development. Developed marks, visible as dark purple images, are generally photographed under white light. Although the technique shows good overall sensitivity (fingerprint marks over 40 years of age have been detected using ninhydrin), weak marks, or marks on dark or multicolored surfaces, may suffer poor contrast.

The dark purple coloration in ninhydrin-developed fingerprints may be modified by treatment with a

metal salt solution. For example, treatment with a zinc(II) salt gives an orange color while that produced by a cadmium(II) salt is red. These color changes are due to the formation of a complex between the Ruhemann's purple (the product from the ninhydrin reaction) and the metal ion (Figure 4). The zinc and cadmium complexes show good luminescence properties that may be exploited for the enhancement of ninhydrin-developed fingerprints. For example, a weak ninhydrin-developed mark may be enhanced by treatment with a zinc salt solution (to form a colored and luminescent complex), followed by visualization under conditions favoring the luminescence emission (in this instance, excitation at 490 nm, emission at 550 nm, with the sample cooled to 77 K using liquid nitrogen to increase the emission intensity).

Several ninhydrin analogs have been synthesized and evaluated as alternatives to the conventional ninhydrin reagent for the development of latent fingerprints on paper surfaces. A number of examples are indicated in Figure 5. Some ninhydrin analogs display increased sensitivity for fingerprint detection, particularly after secondary metal salt treatment. More intense fingerprint luminescence can be achieved in comparison with ninhydrin itself. Unfortunately, the high cost and/or lack of availability of these reagents limits their use for routine work.

**Figure 4** The reaction between ninhydrin and an amino acid, leading to the production of a dark purple compound known as Ruhemann's purple. Further treatment with a metal salt (zinc(II), cadmium(II), or mercury(II)) results in the formation of a luminescent coordination complex. (Reprinted with permission from Lennard CJ, Margot PA, Sterns M, and Marrener RN (1987) Photoluminescent enhancement of ninhydrin developed fingerprints by metal complexation: structural studies of complexes formed between Ruhemann's Purple and Group 11b metal salts. *Journal of Forensic Sciences* 32: 597–605.)

**Figure 5** Several ninhydrin analogs that have been successfully applied to the detection of latent fingerprints on paper surfaces.

### Diazafluorenone

Latent fingerprints on paper may be developed by treatment with a solution of the amino acid sensitive reagent DFO (1,8-diazafluoren-9-one, **Figure 6**). Unlike ninhydrin, heat must be applied to accelerate the reaction. This can be achieved by heating at 100°C for 20 min or by the use of a heat press (180°C for 10 s). Developed marks are pale pinkish-purple in color and exhibit strong room-temperature luminescence (excitation at 470–550 nm, emission at 570–620 nm). The chemical reactions involved are similar to those proposed for ninhydrin and related analogs. At present, DFO is considered to be the most sensitive commercially available chemical reagent for the routine detection of latent fingerprints on paper surfaces.

### Indanedione

A relatively new addition to the range of techniques available for fingerprint detection on paper is the reagent 1,2-indanedione (**Figure 6**). This reagent is chemically similar to ninhydrin and is believed to react with amino acids in a similar fashion. However, unlike ninhydrin, developed marks are luminescent at room temperature without any further treatment. The results from studies conducted in a number of countries suggest that indanedione has a sensitivity comparable to that of DFO on a range of paper substrates. Indanedione is now commercially available and a number of reagent formulations have been proposed.

### Physical Developer

Physical developer (PD) is a fingerprint processing technique for porous surfaces that is sensitive to the

**Figure 6** DFO and indanedione – reagents that react with amino acids to give a luminescent product.

water-insoluble (sebaceous) components of the latent fingerprint deposit. PD can therefore be effective even if the surface has been wet, contrary to amino acid reagents such as ninhydrin and DFO. Fingermarks developed by this procedure are visible as dark gray to black images due to the deposition of silver metal along the print ridges.

PD is an aqueous solution containing silver ions, a ferrous/ferric redox (reduction/oxidation) system, a buffer (citric acid), and a cationic surfactant (generally *n*-dodecylamine acetate). The ferrous (Fe<sup>2+</sup>) ions in solution reduce the silver (Ag<sup>+</sup>) ions to silver metal (Ag<sup>0</sup>), with ferric (Fe<sup>3+</sup>) ions being present to hold back the reaction (eqn [1]):

Citric acid is required to complex with the ferric ions and to maintain a low pH. The action of the surfactant is to inhibit the premature deposition of silver metal by trapping randomly generated silver particles, as they are formed, within positively charged spheres of surfactant molecules known as micelles. The micelles repel the positive silver ions in solution, thereby blocking further silver formation. The PD solution is therefore a delicate balance of ferrous, ferric, and silver ions, stabilized by the presence of citric acid and a surfactant. On contact with the sebaceous material in the fingerprint deposit, the micelles break down and metallic silver is deposited from the solution. As well as detecting fingerprints on items that have been wet, PD complements amino acid sensitive methods on dry paper surfaces in that it can sometimes detect latent marks where other reagents have failed.

The PD technique presents some inconveniences: it is delicate to prepare, the solution is unstable and cannot be stored for longer than about 2 weeks, the method is destructive, some paper surfaces react strongly with the reagent, and no other fingerprint development technique is effective after PD treatment (with the exception of some radioactive detection methods).

## Miscellaneous Techniques

### Multimetal Deposition

Fingerprint development by multimetal deposition (MMD) is a two-step process, the first being immersion of the object in a solution of tetrachloroauric acid (gold(III) chloride) where the active constituent is colloidal gold. Colloidal gold, at a specific pH (between pH 2.5 and 3.9), binds to the peptides and proteins in the latent fingerprint deposit to give a metallic gold image of the fingerprint ridges. (Colloidal gold reagents are commonly employed in biochemistry to detect peptides and proteins.) The second step involves treatment with a modified PD solution that serves to enhance the metallic gold image that is generally quite weak (low contrast). The bound colloidal gold provides a nucleation site around which silver precipitates from the PD solution. A dark-gray to black coloration results that can greatly improve the contrast between the developed print and the substrate.

Many types of surfaces, porous or non-porous, wet or dry, can be treated by the MMD process (e.g., fingerprints may be developed on paper, plastic, expanded polystyrene, and adhesive tape). On some difficult semiporous surfaces such as wax paper and latex gloves, MMD may develop latent fingerprints not detected by other methods.

### Iodine; Iodine-Benzoflavone

Latent fingerprints on a wide variety of surfaces (porous and nonporous) may be detected by fuming with iodine vapor. The iodine is absorbed by the greasy sebaceous material in the fingerprint deposit to give a brown image of the mark. While the technique is simple to apply, it suffers from some major disadvantages:

- iodine vapor is toxic and corrosive;
- contrast in developed prints is generally poor;
- developed marks quickly fade due to reevaporation of absorbed iodine; and
- the technique has limited sensitivity and will generally only detect marks up to several days old.

The contrast and stability of marks fumed with iodine can be improved by secondary treatment with a solution of 7,8-benzoflavone ( $\alpha$ -naphthoflavone). This reagent forms a dark-blue charge transfer complex with the absorbed iodine in the fingerprint deposit.

A combined iodine-benzoflavone reagent can be prepared from two solutions: iodine in a suitable carrier solvent (e.g., cyclohexane or HFC-4310) and

benzoflavone in dichloromethane. The working solution can be used as a spray reagent for the treatment of fixed surfaces at the crime scene. The iodine-benzoflavone spray reagent is effective on a range of different surfaces (e.g., painted surfaces and wallpaper) for prints up to 2 weeks of age, with treated marks becoming visible after a few seconds as dark-blue images.

Fingermarks treated with iodine vapor on human skin or leather may be transferred to a highly polished silver plate by firm contact over several seconds. The transferred fingerprint is then visualized by exposure of the silver plate to a strong UV light source (or sunlight) to produce a dark image of the print. Human skin is one of the most difficult surfaces on which to detect latent fingerprints and very few casework successes have been reported.

### Gentian Violet

A staining solution containing gentian violet (crystal violet) may be employed for the detection of the fatty components in the latent fingerprint deposit. In addition to the stain itself, the solution generally contains phenol to aid the absorption of the stain by the sebaceous material in the fingerprint. An intense purple coloration results. Although the technique may give results on many different surfaces (particularly on nonporous supports contaminated with oils and grease), it is particularly efficient for the detection of latent marks on adhesive surfaces such as pressure-sensitive tapes and films. These surfaces are generally treated by immersion in the reagent, followed by rinsing with water to remove excess stain. In addition, marks developed on dark adhesive tape may be readily transferred onto fixed and washed photographic paper to improve contrast. Gentian violet stain is relatively simple to employ but must be used with caution due to the toxicity of phenol.

### Sticky-Side Powder

Sticky-side powder, a suspension of black fingerprint powder in a detergent solution, is an extremely simple but effective technique for the detection of latent fingerprints on the sticky side of adhesive tape. The technique was developed in Japan in the early 1990s and is now widely employed throughout the world. To prepare the suspension, a detergent solution is mixed with a small amount of black powder until a consistency similar to that of thin paint is achieved. This suspension is then painted onto the adhesive surface using a soft brush (e.g., camel-hair fingerprint brush). After 10–15 s, the adhesive surface is gently rinsed under running tap water. Treated prints are

dark gray to black in color. The process can be repeated if development is weak.

## Fingermarks in Blood

### Optical Detection

Dried blood exhibits a strong absorption maximum at  $\sim 415$  nm. As a result, fingermarks in blood (deposited by fingertips contaminated with blood) can often be enhanced by illumination with a light source filtered to provide violet light at around this wavelength. Dry blood observed under these conditions will appear black. If the surface is reflective or luminescent at this wavelength, good fingerprint contrast will be obtained.

### Amido Black

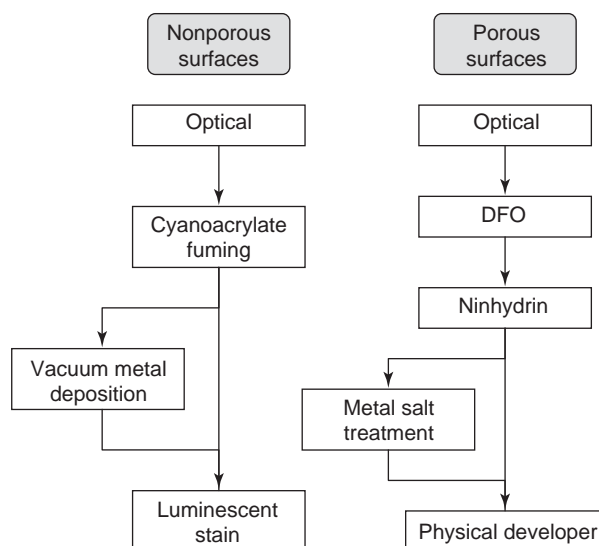

Amido black is a protein stain that may be applied to fingermarks in blood to improve contrast. Blood marks, on either porous or nonporous surfaces, are treated by immersion in a methanolic solution of the stain. The surface is then washed in three destaining solutions to reveal enhanced marks that are dark blue in color. Although the technique is quite effective on nonporous objects, treated marks on porous surfaces such as paper and wood tend to show less contrast due to background staining.

### Diaminobenzidine

The reagent 3,3'-diaminobenzidine (DAB) is a sensitive alternative to protein stains for the enhancement of fingermarks in blood. Blood marks are first fixed with a solution of 5-sulfosalicylic acid. A buffered solution of DAB and hydrogen peroxide is then applied and the reaction allowed to proceed over  $\sim 4$  min. The reaction between hydrogen peroxide and DAB, catalyzed by the peroxidase activity of blood, gives a dark brown insoluble product. Dark brown enhanced marks therefore result. The treatment gives little background coloration, even on porous items, and no destaining procedure is required.

## Fingerprint Detection Sequences

The application of a sequence of fingerprint detection techniques provides the best chance of developing any latent marks that may be present on a particular surface. A correctly chosen combination of methods can increase the total number of fingermarks detected and optimize the amount of detail contained in each mark. However, the techniques must be applied in a logical, predetermined order as the incorrect choice or application of a particular method may preclude the later use of another technique (or, at

**Figure 7** Examples of fingerprint detection sequences for nonporous surfaces, such as glass and plastic, and porous surfaces, such as paper and cardboard. The application of such sequences provides the best chance of detecting any latent fingermarks that may be present.

least, lessen its effectiveness). The choice of a particular sequence will depend on a number of factors including the nature of the support (whether it is porous or nonporous, for example), the environmental conditions to which the object has been exposed (e.g., whether or not the surface has been wet), the presence of any contaminants (e.g., blood), and the likely age of the fingermarks of interest.

Detailed fingerprint detection sequences have been proposed in the literature for various surfaces. Some simple detection sequences are presented in **Figure 7** for general porous surfaces, such as paper and cardboard, and nonporous surfaces, such as glass and plastic. For surfaces that are not commonly encountered, it is recommended that tests be performed on a similar surface to determine what techniques, and what sequence of techniques, should be applied on the evidential item.

## Introduction

Glass is one of the major evidence types encountered in forensic science. In a typical case, small glass fragments recovered from the clothing of a suspect are compared with broken glass from the scene of a crime. Characterization of glass requires a combination of physical and chemical techniques that can be applied to small fragments. Refractive index (RI) is the most informative physical property. A wide range of chemical techniques is available to determine the elemental composition of the glass. Interpretation of results depends on many factors, and although assisted by statistical methods, relies largely on the knowledge and experience of the scientist. The making and forming of glass by melting is an art that originated in Egypt and spread slowly westward. In the sixteenth century, Venice became an important center of progress and glass making flourished. The first methods for the continuous production of window glass were introduced early in the twentieth century, and a further major development was the invention of float glass in 1959.

For the purposes of forensic science, glass can be regarded as a hard brittle amorphous solid, breaking with a conchoidal fracture and formed from the fusion of inorganic oxides. A glass can also be regarded as a supercooled liquid, with the random nature of the liquid frozen into the solid structure. Crystal nucleation and growth is prevented by rapid cooling through the critical region.

Silica ( $\text{SiO}_2$ ) is the most important of the glass-forming oxides although the chemical composition of glasses can vary greatly. The main components of commercially important glasses are shown in **Table 1**.

In addition, a number of trace elements will also be present. These may be deliberately added to give a color or tint to the glass, or may represent impurities in the major components. Elements such as lithium, fluorine, sulfur, chlorine, scandium, titanium, chromium, manganese, cobalt, nickel, zinc, arsenic, selenium, rubidium, strontium, cesium, lanthanum, cerium, tantalum, and uranium fall into this category, and some have considerable importance in forensic science either in identifying the source of a glass fragment or in discriminating between glasses from different sources.

## Glass as Forensic Evidence

The main types of glass dealt with in forensic science casework are listed in **Table 2**. Although total production of container glass considerably exceeds that of other types, glass from buildings and vehicles

## Introduction

Glass is one of the major evidence types encountered in forensic science. In a typical case, small glass fragments recovered from the clothing of a suspect are compared with broken glass from the scene of a crime. Characterization of glass requires a combination of physical and chemical techniques that can be applied to small fragments. Refractive index (RI) is the most informative physical property. A wide range of chemical techniques is available to determine the elemental composition of the glass. Interpretation of results depends on many factors, and although assisted by statistical methods, relies largely on the knowledge and experience of the scientist. The making and forming of glass by melting is an art that originated in Egypt and spread slowly westward. In the sixteenth century, Venice became an important center of progress and glass making flourished. The first methods for the continuous production of window glass were introduced early in the twentieth century, and a further major development was the invention of float glass in 1959.

For the purposes of forensic science, glass can be regarded as a hard brittle amorphous solid, breaking with a conchoidal fracture and formed from the fusion of inorganic oxides. A glass can also be regarded as a supercooled liquid, with the random nature of the liquid frozen into the solid structure. Crystal nucleation and growth is prevented by rapid cooling through the critical region.

Silica (SiO<sub>2</sub>) is the most important of the glass-forming oxides although the chemical composition of glasses can vary greatly. The main components of commercially important glasses are shown in **Table 1**.

In addition, a number of trace elements will also be present. These may be deliberately added to give a color or tint to the glass, or may represent impurities in the major components. Elements such as lithium, fluorine, sulfur, chlorine, scandium, titanium, chromium, manganese, cobalt, nickel, zinc, arsenic, selenium, rubidium, strontium, cesium, lanthanum, cerium, tantalum, and uranium fall into this category, and some have considerable importance in forensic science either in identifying the source of a glass fragment or in discriminating between glasses from different sources.

## Glass as Forensic Evidence

The main types of glass dealt with in forensic science casework are listed in **Table 2**. Although total production of container glass considerably exceeds that of other types, glass from buildings and vehicles

**Table 1** Main components of glass encountered in forensic science laboratories

<i>Component</i>	<i>Typical source of raw material</i>	<i>Function in the glass</i>
SiO <sub>2</sub>	High-quality sand or sandstone	Glass-forming oxide, sometimes partially replaced by B <sub>2</sub> O <sub>3</sub>
Na <sub>2</sub> O	Na <sub>2</sub> CO <sub>3</sub> – as soda ash	Reduces melting point and lowers viscosity
K <sub>2</sub> O	Depends on sources of other raw materials – not deliberately added	Similar to Na <sub>2</sub> O
MgO	Dolomite	Permits slower setting and reduces crack formation
CaO	Limestone	Decreases solubility of sodium silicates and hence increases chemical durability; increases fluidity when hot and allows for more rapid cooling
Al <sub>2</sub> O <sub>3</sub>	Feldspars, blast furnace slag	Increases mechanical strength and inhibits devitrification; raises the viscosity of the melt
Fe <sub>2</sub> O <sub>3</sub>	Impurity associated with other raw materials, especially the sand	Discolors glass – used to introduce a tint
BaO	Barytes	Increases durability, and also increases refractive index
PbO	Lead oxide, lead sulfide	Increases refractive index, enhances appearance, e.g., lead crystal wine glasses
B <sub>2</sub> O <sub>3</sub>	Borax	Increases scratch resistance and durability

**Table 2** Main types of glass encountered in forensic science casework

<i>Type</i>	<i>Manufacturing process</i>	<i>End use</i>
Float	Glass flows from the furnace onto a layer of molten tin in a controlled reducing atmosphere	Wide – especially for buildings, vehicles and mirrors. Has largely replaced other types of flat glass
Sheet	Drawn vertically as a continuous ribbon	Horticultural, domestic where the appearance is not critical
Plate	Initially cast into trays, later a continuous process. Glass is ground and polished to produce a flat surface	Buildings, mirrors. Superseded by float glass
Patterned	Partly cooled glass ribbon passes through metal rollers, one of which bears the pattern	Buildings
Wire reinforced	Wire mesh is sandwiched between two layers of partly cooled glass. Can be clear or patterned	Buildings – increases security and fire resistance – as compared to standard glass
Toughened	Rapid cooling of glass to introduce a high level of stress. Usually float glass	Motor vehicles, safety glass in buildings
Laminated	Thin sheets of glass are bonded to clear plastic	Motor vehicle windscreens, security glass
Containers and tableware	Blow/molding process	Packaging industry, especially food and drinks, drinking glasses

forms the majority of glass examined in forensic science laboratories. Float glass is used almost exclusively for clear windows although, as glass is a very durable material, many older sources of glass are also routinely encountered. In common with other brittle materials, when a glass object such as a window or container breaks, many small sharp-edged glass fragments are produced. In particular, when a window is broken by an applied force such as bodily pressure, or by striking with a solid object, the glass will bend, causing the surface on the side of the applied force to be compressed and the opposite surface to be in a state of tension. Stress is relieved by the formation of cracks that rapidly propagate through the thickness of the glass from the remote side to the side bearing the breaking force. Small fragments flake off along the edges of the cracks, and can be

projected for a distance of at least 3 m from the window. A considerable proportion of these fragments will include part of the original surface of the glass, and the great majority will be less than 1 mm in size. Such fragments are readily transferred to the clothing of a person who is nearby. Glass fragments can also be transferred by contact with sharp edges of freshly broken glass. The clothing is searched and recovered glass fragments are compared with a known control sample of glass from the scene of the crime.

## Measurement of Physical Properties

Typical glass fragments recovered from clothing will have a largest dimension in the range 0.2–1.0 mm and a mass of 100 µg or less. A considerable

proportion of such fragments will have a surface that represents part of the original surface of the unbroken glass object. Although larger pieces of glass are available as control samples from the known source of broken glass, it follows that all the most significant comparison techniques have been developed to deal with small fragments.

The two most widely measured physical properties are density and RI. These two properties are highly correlated in glass, consequently if one is measured with sufficient accuracy and precision, little additional information is to be gained by measuring the other. Optical dispersion and physical stress are the other properties that are measured in small glass fragments. Examination of glass surfaces also provides useful information.

### Density

Until about 1980, density was the most important physical property used for glass comparisons in forensic science laboratories. Although largely replaced by RI measurement, it is still currently used, and is particularly valuable as a screening technique for large numbers of glass fragments.

Two main methods have been developed for density measurement. Both methods are based on a mixture of two liquid components, one less dense and the other denser than glass. Bromohydrocarbons are typically used. The first is a comparative method in which the components are combined to give a liquid of uniform density that is equal to that of the control glass sample. Fragments of control glass will suspend in the liquid. Recovered fragments will also suspend if they have the same densities as the control glass, otherwise they will either float or sink. The density of the liquid mixture can be altered by either changing the temperature or by adding more of one of the liquid components.

In the second method, a stable density gradient is formed in a tall container by introducing a mixture of the two liquid components. As the container is filled, the density of the liquid mixture is decreased by altering the proportions of the components. Fragments of glass are added to the column of liquid and will sink to a position at which the liquid has the same density as the glass. Standards of known density are added to the column and the densities of the glass under test can be obtained by interpolation. An accuracy of  $0.5 \text{ mg ml}^{-1}$  is typically achieved.

The precision of density measurement is affected by the shape and size of the glass fragments and also by the presence of surface deposits or cracks. The liquids used are noxious and recovery of small glass fragments is not easy. These disadvantages are overcome by measurement of RI.

### Refractive Index

Refractive index is the most useful physical property in forensic glass characterization. It can be measured to a high degree of accuracy and precision, which is essentially independent of fragment size. The RI of a glass depends upon the combination of raw materials used, together with the nature of the manufacturing process.

The RI of glasses examined in forensic science laboratories generally falls in the narrow range of 1.51–1.54, with the exception of borosilicate glass from motor vehicle headlamp lenses, which typically has an RI of 1.475–1.480. As RI measurement can discriminate glasses with RI differences of 0.0001, glasses can be divided into a large number of groups by this technique.

The inherent variation in RI within the bulk of a single sheet of glass is of the order of 0.00005–0.0001, so greater accuracy and precision of measurement is unlikely to increase the discriminating power of this technique.

Current techniques of RI measurement are based on the fact that the RI of a liquid changes with temperature at a much greater rate than that of a solid. Typical RI/temperature coefficients are  $4 \times 10^{-4} \text{ C}^{-1}$  for a liquid, and  $1 \times 10^{-6} \text{ C}^{-1}$  for a glass.

A fragment of glass is immersed in a colorless oil and placed on a hotstage that is programmed to change temperature with time at a linear rate. The oil is calibrated by glass standards of known RI. This enables the RI of the oil to be calculated for any particular hotstage temperature.

The glass fragment is viewed by transmitted light through a phase contrast microscope. Monochromatic light from a sodium lamp or filtered light of a narrow range of wavelength produces a bright line around the edge of the fragment. The temperature of the hotstage is varied until the oil has the same RI as the glass. At this point, known as the match point temperature, the bright line around the fragment disappears. The match point of a glass fragment can be detected automatically, although the image of the fragment is displayed on a screen throughout the measuring process.

### Dispersion

The RI of a material varies with wavelength and this wavelength dependence, known as dispersion, is particularly useful for identifying minerals. The dispersion of a glass can be estimated by measuring the RI at three different wavelengths. Although dispersion is quite widely measured in the USA, recent studies have suggested that compared with RI measurement at a single wavelength, limited additional

discrimination is achieved when dealing with glass of modern production.

### Physical Stress

Thermal and structural stresses are introduced into glass during the manufacturing process. Above a temperature known as the annealing point (typically about 600°C for float glass), the structure of the glass readily changes with any increase in temperature and therefore any stress will be rapidly relieved. Below the annealing point, the time taken for the glass to reach structural equilibrium increases rapidly as the temperature falls, and below a temperature known as the strain point (typically ~450°C), the structure of the glass is essentially fixed and does not change with temperature or time. One of the final stages in glass manufacture is to remove residual stress by annealing the glass; that is, maintaining it at a fixed temperature and then allowing it to cool at a slow controlled rate. Toughened glass is produced by rapidly cooling below the annealing point in order to introduce a high degree of stress. The interior of the glass is in tensile stress and the two surfaces are in compressive stress. This makes the glass more resistant to low velocity blunt impacts, hence its use in motor vehicles.

The high degree of stress in a toughened glass causes it to have a lower RI than ordinary glass of the same elemental composition. Some of the stress is relieved when the glass breaks, but the residual stress in a fragment of toughened glass is considerably greater than that remaining in a fragment from a nontoughened glass source. This high stress level can be revealed by reannealing the glass. Relieving the stress increases the RI. The increase depends on the reannealing schedule. A typical increase in RI for a toughened glass would be 0.0015, whereas the increase for most nontoughened glasses would be less than 0.0005. In glasses with a very low stress level, reannealing may increase the stress, causing the RI to decrease. Reannealing, therefore, provides a technique for distinguishing between fragments of toughened and nontoughened glasses.

### Surface Characteristics

Examination of any original surface present on a recovered glass fragment can provide information on its probable origin. Interference microscopy is one of the techniques used to visualize the surface features. Monochromatic light is split into two beams, one reflected from the surface of the fragment under test and the other from the surface of a reference mirror. Recombination of the beams produces an interferogram, interpretation of which can assist in determining the topography of the surface. Parallel lines

(or fringes) indicate a flat original surface. Curved lined or irregular patterns are more difficult to interpret and require comparison with the surface of the control glass sample, or with fringe patterns produced by known glass surfaces.

Differential interference contrast microscopy is also used to enhance surface features. Plane polarized light is split by a prism into two beams that travel in slightly different directions. The beams are reflected from the surface of the glass fragment, and then recombined to produce an interference pattern that gives surface features a three-dimensional appearance. A useful application of this technique is in examining the scratches in glass fragments from the outer surface of a vehicle windscreen, where the wiper blades have been in contact with the glass surface.

The surface of float glass that has been in contact with molten tin gives a yellow fluorescence under ultraviolet radiation at 254 nm. This fluorescence can be seen in small glass fragments. The presence of tin in the surface layer of float glass produces a higher RI than that of the bulk glass. The difference between the surface and bulk RI is difficult to quantify, but is typically of the order of 0.003 when measured by the oil immersion method.

### Elemental Analysis

Measurement of physical properties enables glass fragments to be divided into many different groups, but relatively little information is obtained as to the source of the broken glass object from which the fragments have originated. Elemental analysis can assist in:

1. classifying the type of the glass, e.g., window, container, or tableware;
2. identifying the probable country of origin;
3. discriminating between samples that are indistinguishable in physical properties;
4. assessing the evidential significance of matching glass.

Elements that are useful for classification and discrimination include lithium, aluminum, magnesium, potassium, iron, manganese, arsenic, barium, rubidium, and strontium (Table 3).

An ideal method of elemental analysis for glass should:

1. be nondestructive; the sample should be available for further analysis;
2. be capable of analyzing the smallest glass fragments recovered in casework;

**Table 3** Typical glass compositions

Glass type	Composition (as % oxides by wt.)							
	SiO <sub>2</sub>	Na <sub>2</sub> O	K <sub>2</sub> O	MgO	CaO	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	BaO
Float	72.6	13.0	0.6	3.9	8.4	1.0	0.1	
Plate	72.5	13.2	0.7	3.8	8.1	1.3	0.2	
Container	73.0	14.0		0.3	10.9	1.4		
Drinking glass	73.8	15.3		3.8	8.1	1.3		
Bulb	70.3	16.4	1.0	3.4	5.5	1.4		2.0
Television tube	64.0	9.6	6.5	1.2	1.7	3.3	0.1	12.6

**Table 4** Current methods of elemental analysis for glass in forensic science

Probable year of introduction	Method	Destructive technique	Full range of elements detected	Further information
1970	Neutron activation analysis (NAA)	No	Yes	Pitts and Kratochvil (1991)
1973	Energy dispersive X-ray analysis using scanning electron microscopy (SEM-EDX)	No	No	Andrasko and Maehly (1978)

1979	Inductively coupled plasma atomic emission spectroscopy (ICP-AES)	Yes	Yes	Catterick and Hickman (1979)
1989	Inductively coupled plasma mass spectrometry (ICP-MS)	Yes	Yes	Zurhaar and Mullings (1990)

3. have high absolute and relative sensitivity;
4. be able to detect and quantify all relevant elements;
5. be cost-effective, with a rapid throughput of samples.

A wide range of techniques has been used for the analysis of glass fragments. Several of these techniques, including atomic absorption spectrometry, DC arc emission spectrography, and spark source mass spectrometry are no longer in routine use. Historically, much of the early analytical effort was directed toward classification of the glass, but at the present time there is a greater emphasis on discrimination and on improving the assessment of evidential significance. Current techniques are listed in Table 4 and are briefly described below.

#### Neutron Activation Analysis (NAA)

Glass samples are placed in plastic vials and irradiated in the neutron flux of a nuclear reactor. Short irradiation times produce low levels of residual radiation, enabling the samples to be handled safely within a few days of analysis. Data are acquired by a germanium detector and multichannel analyzer. Most

elements of interest possess several radioactive isotopes, enabling some degree of choice between detecting either a short-lived or long-lived radionuclide.

Analysis of variance techniques can be used to study differences between glass samples, without reference to quantitative elemental standards.

#### Scanning Electron Microscopy-Energy Dispersive X-Ray Microanalysis (SEM-EDX)

Glass samples are presented to the scanning electron microscope on a stub. The preferred method is to encapsulate the glass fragment in a resin, then grind and polish to produce a flat surface. A quicker alternative is to mount the fragment directly on a carbon stub, but this method tends to give lower analytical precision. In either method, the fragment is coated with a thin layer of carbon to make the surface electrically conductive. A typical stub will bear at least one glass standard of known composition, together with control and recovered fragments. The prepared stub is mounted on a movable stage in the microscope. A flat area of the sample is selected for analysis by viewing the SEM video display. Bombarding the sample with an electron beam produces

an energy spectrum that is composed of peaks due to characteristic X-rays, superimposed on a relatively featureless background. Standard data processing techniques are used to compensate for factors that affect peak intensities, enabling reliable quantitative results to be obtained.

### **Energy Dispersive X-Ray Fluorescence (EDXRF) Spectrometry**

Glass fragments are cleaned, mounted on a plastic probe, and placed in the XRF spectrometer. The resultant energy spectrum is collected by a multichannel analyzer. Secondary X-rays from the detectable elements within the glass produce characteristic peaks in the energy spectrum. The detected peak intensity for a particular element in a glass fragment depends upon the amount present, and also on other factors including the geometry of the fragment. When fragments are to be compared they should be closely matched in shape and size. Available instruments are not able to analyze the smallest glass fragments encountered in casework, and it is not easy to obtain reliable quantitative results by this technique.

### **Inductively Coupled Plasma-Atomic Emission Spectrometry (ICP-AES)**

Glass fragments are cleaned, and then dissolved in a mixture of hydrofluoric and hydrochloric acids. A suitable element is added as an internal standard. The solution is nebulized and the resultant aerosol is introduced into the plasma by argon carrier gas. The intensities of the emission lines of the chosen elements are measured sequentially. Quantitative results are achieved by comparing intensities against those obtained from analysis of multielement standard solutions.

### **Inductively Coupled Plasma-Mass Spectrometry (ICP-MS)**

Sample preparation is similar to that required for ICP-AES, involving nebulizing a solution of the dissolved glass fragment into the ICP-MS system. Data are accumulated sequentially on all measured isotope intensities over the selected mass range. Application of appropriate correction factors allows the element concentrations to be calculated from the mass of the fragment and the volume of the solution. The instrumentation is checked by repeated analyses of standard glasses with known elemental compositions.

### **Advantages and Disadvantages**

Not one of the above methods is ideal in all respects. For a nondestructive analysis, the SEM-EDX and EDXRF techniques complement each other well, but

not all useful elements can be detected. Current developments in EDXRF spectrometry, including altering the geometry of the instrument with respect to the excitation source and the sample, have the potential to increase the power of this technique considerably.

The most generally used destructive technique is ICP-AES, although it cannot effectively deal with the smallest casework samples. ICP-MS is a newer technique that has superseded spark source mass spectrometry. A limitation of NAA is the requirement of a nuclear reactor as an energy source so it is unlikely that this technique will become widely used.

### **Surface Analysis**

As a consequence of the manufacturing process, the surface of a sheet of glass is likely to have a slightly different chemical composition from that of the bulk. In float glass, the two surfaces will be very different in composition, since one has been in contact with a layer of molten tin whereas the other has not. Some reusable containers may receive a surface coating during manufacture, to increase scratch resistance and strength. Atmospheric weathering may change the surface composition of a glass by leaching out the more soluble components.

A wide range of analytical techniques has been used by the glass industry to examine glass surfaces, but in general these are not applicable to small fragments and consequently have not been developed for use in forensic science. However, SEM-EDX does not suffer from this size limitation and can provide valuable information on the surface composition of glass fragments.

### **Interpretation of Results**

A typical forensic case concerning glass involves a search for and recovery of glass fragments, surface examination, measurement of RI, and elemental analysis. A two-stage approach is widely used to assess the results of the physical and chemical comparisons. The first stage is to determine how many types of recovered glass are present, and whether or not any match the control with respect to the measured properties. Graphical displays and statistical tests are used to assist in this process. The second stage is to assess the significance of any matching glass, usually by reference to a data collection. A type of glass that is rarely found on clothing is likely to be of greater evidential value than a type that is frequently encountered. The two-stage approach works well for simple cases, but it is difficult to apply in complex cases involving more than one control sample and several types of recovered glass.

An alternative approach, which encapsulates the matching and significance aspects of a comparison in a single stage, is to express the scientific evidence as a likelihood ratio of the form:

$$\frac{\text{probability of scientific findings} \\ \text{if suspect involved in crime}}{\text{probability of scientific findings} \\ \text{if suspect not involved in crime}}$$

Calculation of the numerator involves assessing the probability that glass fragments of a particular type will be transferred to and retained on the clothing of a suspect, given the circumstances of the case. Calculation of the denominator involves assessing the probability of finding the glass on the clothing of the suspect, given that he or she is a randomly selected member of an appropriate population.

Regardless of which method of interpretation is used, the evidence may have to be evaluated in the light of several different possible explanations. Combining all the relevant information to reach a final conclusion depends largely upon the experience of the scientist.

Knowledge-based computer systems can be used to assist the scientist by providing an inferential framework and access to relevant databases, including results of previous cases. It would be very difficult to construct a comprehensive statistical model to deal with all cases involving glass evidence. A compromise approach that combines statistical methods with expert experience and judgment is likely to be the most effective.

## Casework Examples

### Burglary at a Public House

The premises were illegally entered by smashing a ground floor window. Money was stolen from several gaming and video machines. A few minutes later a suspect was arrested nearby. He had a pair of gloves in the pocket of his coat. Several hundred glass fragments were recovered from each glove, and several hundred more from the surface and pockets of his coat. The RI of 10 of the fragments was measured and all were found to match the control float glass from the broken window of the public house. Interference microscopy showed that two of the 10 fragments possessed an original flat surface. The control glass and one of the recovered fragments also gave a similar result when analyzed by SEM-EDX. Measurement of these physical and chemical properties showed that the glass was a type that is fairly frequently encountered in casework.

It is very unusual for such a large number of glass fragments to be found on items of clothing. The conclusion reached was that the wearer of the gloves and coat had been in recent contact with breaking or broken glass and that the findings provided very strong support for the allegation that he was involved in the incident in question.

### Criminal Damage at a Craft Shop

The shop window was broken and a Ford Escort motor car was witnessed leaving the scene. The car was stopped ~15 miles from the scene and the occupant was arrested. A baseball bat was found on the rear seat of the vehicle. On examination the bat was found to have numerous recent cuts in the surface of the wood. Many of these cuts contained embedded and crushed glass fragments. Fragments from five of the cuts were examined and found to match the control sample of float glass from the shop in RI and elemental composition. The results, as shown in **Figure 1**, were typical of a modern mass-produced float glass. The forensic scientist concluded that with regard to the alleged circumstances of the incident, the scientific evidence strongly supported the view that the bat had been in forcible contact with the broken window from the shop.

### Burglary at a Post Office

The sound of breaking glass was heard at a Post Office, and two men were seen running away. Two men were later arrested and items of clothing were obtained from them. A control glass sample was obtained from the broken window. Five types of glass were recovered from the clothing of the first man and six types from the clothing of the second man. RI measurement showed that one of the types of recovered glass from each man matched the glass

**Figure 1** Analysis by SEM-EDX of glass from a case involving criminal damage to a craft shop. The RI of the glass was 1.5175; glass recovered from cuts in a baseball bat gave similar results to glass from the broken window.

**Figure 2** Analysis by SEM-EDX of glass from a post office burglary; glass recovered from the clothing of the two suspects gave similar results to control glass from the broken window.

from the Post Office. Analysis of the control and recovered glass by SEM-EDX indicated that the glass was of an old type that is rarely encountered in casework. The results of the analysis are shown in **Figure 2**. Unlike modern window glass, the elements potassium and magnesium were not detected. The conclusion reached was that with regard to the alleged circumstances, the matching glass recovered from the clothing provided very strong support for the view that the two men were involved in the incident in question.

## Introduction

The identification of a substance as gunshot residue (GSR) can be vitally important in cases where

firearms have been discharged. Not only can GSR be used to identify bullet holes, it can also yield useful information as to firing distance, identification of a suspect as having recently used a firearm, and in some circumstances may help distinguish suicide from suspicious death.

When the trigger of a firearm is depressed, a hammer or firing pin strikes the base of a cartridge that sets off a series of chemical reactions that rapidly results in the projectile (or projectiles in the case of shot guns) being propelled from the cartridge case and out of the weapon.

**Figure 1** Schematic diagram of firearm cartridges.

Cartridges, whether they are based on a single projectile (bullet) or many (shot), have the same basic architecture (see **Figure 1**). At the base of the cartridge is a small amount of shock-sensitive chemical mixture; this is termed the primer. Above the primer is an explosive mixture, the propellant, with the projectile (bullet or shot) clamped at the top of the cartridge. In the case of shot there may also be wadding material to hold the multiple projectiles separate from the propellant.

On depression of the trigger, the firing pin or hammer strikes the base of the cartridge case initiating the explosion of the shock-sensitive primer. The energy generated by this reaction in turn causes the rapid combustion of the propellant mixture and the generation of gases at high temperature and pressure. The pressure of gas causes the projectile(s) to be ejected from the cartridge and down the barrel of the firearm. The propellant continues to burn behind the projectile all the way down the barrel, thus resulting in acceleration of the projectile(s) due to the increased volume of gas that is produced.

GSR arises from the cooling and condensation of the gases produced by the combustion reactions within the firearm. Most of the gases are expelled down the barrel of the weapon; however, significant quantities also escape from the many openings present within the weapon such as the breech, ejection ports, and trigger. As the gases cool and condense, they form the particles that are referred to as GSR. The residues may be associated with the primer cap, propellant, bullet (slug/shot), bullet jacket and lubricant, cartridge case, and firearm barrel. Escaping GSR can be deposited on anyone or anything within close enough range of the discharging weapon. For example, if a victim is shot at short range, there is likelihood that any bullet hole in their clothing (or body) will be surrounded by deposits of GSR (see **Figure 2**). Besides identifying a hole as being caused by a bullet, the size of the deposits of residue can be used in estimations of shooting distance. If a suspect has discharged a firearm, GSR will

**Figure 2** Cloth sample showing spread of GSR around a bullet hole. (Photograph Kent Agg, Deakin University.)

be found on the hand that held the weapon and also on their clothing.

Key to forensic investigations such as these is the positive identification of suspect materials as GSR. The analytical methods that have been utilized over the years for the identification of GSR can be divided into two classes, based on determination of

- inorganic species such as, lead, barium, and antimony, which are mainly present in the primer and the bullet (but which also includes nitrate and nitrite ions from the propellant); and
- organic compounds from the propellant, which serve various roles in the discharge of the firearm.

Identification of these residues, particularly when combined with consideration of the location and pattern of any residues detected, can give invaluable information to investigators and courts of law.

## Chemical Species Contributing to GSR

The various compounds that can contribute to GSR come from a variety of sources including the firearm itself as well as the cartridge and its contents. This wide range of chemical species described below is classified by their source; **Figure 3** gives the chemical structures for some of the more common compounds.

### Propellants

The first propellant employed for firearms was black powder (also colloquially known as gunpowder), which is a mixture of charcoal (carbon), sulfur, and potassium nitrate, with typical proportions of 15% carbon, 10% sulfur, and 75% potassium nitrate.

**Figure 3** Some examples of compounds contributing to GSR.

Smokeless propellants were developed toward the end of the nineteenth century and are based on nitrocellulose, which was produced by the nitration of cotton linters or wood pulp using a mixture of nitric and sulfuric acids. These propellants are classified as either being single base with nitrocellulose as the sole propellant, double base containing nitrocellulose and nitroglycerine, and triple base also containing nitroguanidine (picrite). The latter kind of propellant is generally restricted to military uses.

In addition to the chemical composition, the grain size and shape of the propellant is also of importance as it can have a marked influence on the rate of burning.

Single- and double-base propellant grains can have various morphologies, including long-, short-, or multiperforated tubes, short rods (macaroni), rings, cubes, flakes, strips, disks, balls, and flattened balls.

The combustion properties of the propellant can also be altered by using various surface coatings and additives such as stabilizers, oxidizers, plasticizers or gelatinizers, and deterrents or retardants.

Graphite, centralites (substituted phenylureas), dibutyl phthalate, camphor, and dinitrotoluene isomers are the commonly used retardants. Phthalates (such as dibutyl and diamyl) and camphor can also act as plasticizers during the manufacturing process.

Stabilizers that have been utilized in propellant formulations include diphenylamine, Vaseline (substituted diphenylureas), Arkadite (diphenylurea), centralites, and various substituted urethanes. Although rare, carbene, a polyacetylene, can be added to some fast-burning double-base propellants as an accelerator. This type of propellant is likely to only be encountered in large caliber military ammunition.

### Primers

Primers are designed to ensure that the propellant is ignited by rapid combustion instead of explosive detonation. In addition to a shock-sensitive detonator or initiator, primers also contain oxidizing agents, fuel compounds, sensitizers, fillers, and binding agents.

The earliest primers were based on mixtures of potassium chlorate, sulfur, and carbon (charcoal); these were replaced in the 1830s by mixtures utilizing mercury fulminate and lead azide as initiators. However, due to the corrosive effect of mercury fulminate, these primers have been superseded by formulations based on lead styphnate.

The majority of primers today are based on the 'synoxyd' primer, first introduced in 1928. These utilize lead styphnate as the initiator, antimony sulfide as the fuel and frictionator (a substance that helps to efficiently pass on the energy from compression of the primer cap), and barium nitrate as the oxidizer. Other compounds that may also be present include calcium silicide, acting as a fuel and frictionator; gum arabic, a fuel and binder; oxidizers such as lead dioxide, lead nitrate, and lead hypophosphite; ground glass or aluminum powder as frictionators; tetrazene, a sensitizer; and various other gums and resins as binders.

In more recent years there has been the development of lead-free primers based on the organic shock-sensitive initiator dinol (diazodinitrophenol) in place of the lead styphnate. Commercial formulations of dinol-based primer have been developed which include mixtures such as dinol, zinc peroxide, metallic titanium, and tetrazene; dinol, manganese(IV) oxide, and metallic aluminum; and dinol, antimony sulfide, and barium nitrate.

### Bullets, Cartridge Case, and Primer Cap

Bullets and shot are usually lead or lead-antimony alloys of between 0.5% and 3% antimony to harden the lead (in rare cases tin can be the hardener). Bullets can also be semijacketed, tipped, or fully jacketed, with copper and copper alloys with zinc and/or tin being the most common materials. Bullet jackets

can also be coated with chrome, nickel, cupro-nickel, and zinc.

Cartridge cases are generally brass (~70% copper and 30% zinc) and can be plated with nickel, aluminum, or steel. Steel coated with zinc or copper has been used but rarely. Shotgun cartridges are usually fabricated from cardboard or polyethylene with a brass base.

The primer cap is usually brass or copper that is often nickel plated; galvanized steel caps have also been employed.

### Other Sources of Residues

In addition to the cartridge and its contents, other substances present within the firearm such as oil and rust can also be sources of residue.

## Sampling and Sample Preparation Techniques

The process of sampling is a vital step in GSR analysis. Contamination is a significant issue and the location and distribution of particles, not only their identification as GSR, is often of great importance. Consequently, the method of sampling will depend on the nature of the investigation being carried out and the subsequent analysis method. The most commonly applied method of collection is swabbing using fabric swabs moistened with dilute (usually nitric) acid solutions, water, and a variety of solvents, depending on the analytical technique to be used. This technique partially solubilizes the GSR. It is of vital importance that the swabs and solvent used are free of contaminants and it is essential that a blank swab with solvent is collected at the time of sampling in order to detect any background contamination.

Vacuum lifting by collection of GSR from surfaces by vacuuming through a series of filters of different pore size has also been used. This method is useful particularly when recovering residues from clothing. However, its very efficiency can be a disadvantage as all particulates, GSR and otherwise, will be collected, with GSR being present only in very small proportions. Additionally, due to vacuuming being a relatively vigorous technique, any attempts to distinguish more recently deposited particles on the surface from older particulate matter within the weave of the cloth will be foiled.

Tape lifting, where samples are simply, quickly, and directly collected onto adhesive tape, is the main method of collection for analysis by scanning electron microscopy (see below). This technique with subsequent dissolution of the residues in a suitable solvent has also been used to collect GSR prior to

analysis by separation methods such as capillary electrophoresis.

## Analytical Methods for the Detection and Identification of GSR

A wide variety of analytical methods have been applied to the detection and identification of GSR. In common with other forensic analyses they can be divided into color (chemical) spot tests for initial screening and instrumental methods. The situation with GSR is complicated by the issues of contamination and by the fact that many of the chemical components seen in GSR may have other innocent or environmental sources.

### Color (Chemical) Tests

Chemical reactions that provide a characteristic color on reaction with components of GSR have widely been used. They have the advantage that they can often be carried out in the field with little or no scientific instrumentation and yield a rapid result. However, this result requires careful interpretation as the reactions have been shown to be nonspecific and have poor sensitivity. Consequently, they can only be considered a preliminary screening test, and are not suitable as a confirmation of identification of GSR.

The earliest method of detection of GSR on the hands and skin of a suspected shooter was the dermal nitrate or paraffin test. This is based upon the color reaction of nitrites and nitrates with diphenylamine in sulfuric acid. This reaction is not specific to nitrates and nitrites and will give positive results with other oxidizing agents such as chlorates, dichromates, iodates, bromates, permanganates, and higher metal oxides. This test can also give false negative results in certain situations where it is known that a person has fired a weapon and has not yet washed his or her hands. Consequently, this procedure is no longer recommended.

The Griess test similarly involves a reagent ( $\alpha$ -naphthylamine, and sulfanilic acid in acetic acid) targeting nitrites. This test is based on the formation of a diazonium salt when nitrite in acid solution reacts with a primary aromatic amine. The nitrites react with sulfanilic acid in acetic acid to form a diazonium ion that is then coupled to  $\alpha$ -naphthylamine to form a red azo dye. The reported carcinogen  $\alpha$ -naphthylamine can be replaced with Marshall's reagent *N*-(1-naphthyl)-ethylenediamine or  $\alpha$ -naphthol. A permanent reproduction of a GSR pattern can be produced by utilizing the reagent immobilized on desensitized photographic paper, which is then

placed against the bullet hole and surrounding residue and subjected to a heat treatment. Dark red spots are observed corresponding to the partially burnt GSR grains being transferred to the photographic paper. Other color tests for inorganic compounds include the sodium rhodizonate test where the reagent reacts with lead to form a violet-blue color and the rubeanic acid test where copper or nickel react to produce colored precipitates.

Due to the potential of environmental contaminants these tests are generally not used to detect GSR particles in the first instance, rather they are used to visualize GSR distribution around bullet holes.

### Instrumental Analysis

Several instrumental methods have been applied to the determination of the various components of GSR. To date most of the procedures used operationally have concentrated on the inorganic fraction of GSR. In particular, the methods of elemental analysis targeting lead, barium, and antimony have widely been used, as this elemental combination is characteristic of most GSR. More recently research interest has focused on the organic components of GSR.

### Neutron Activation Analysis

Neutron activation analysis (NAA) is a nondestructive method based upon the conversion of stable isotopes of chemical elements to unstable radioactive isotopes by irradiation with thermal neutrons within a nuclear reactor. If the ensuing decay of irradiated nuclides occurs via  $\gamma$ -radiation, a  $\gamma$ -ray spectrum can be obtained on a  $\gamma$ -spectrometer, which is characteristic of a specific element.

NAA can be used for identification of antimony and barium in bulk samples (as opposed to single particles) of GSR. It is highly sensitive but is not applicable to lead and requires an intense neutron source such as a suitable nuclear reactor. Despite these limitations NAA has found application to GSR analysis in forensic investigations.

### Atomic Absorption Spectroscopy and Related Techniques

Atomic absorption spectroscopy (AAS) has found wide application as a bulk analysis technique for GSR. This method of analysis is capable of sequentially determining lead, antimony, and barium; however, in order to detect the low concentration of these species that may be present in GSR, the more sensitive flameless AAS techniques such as electrothermal atomization are required.

More recently, inductively coupled plasma atomic emission spectroscopy has also been applied to the analysis of GSR; however, it has not found widespread use, presumably due to the high cost of the instrumentation.

### Scanning Electron Microscopy

Scanning electron microscopy in combination with X-ray spectroscopy, particularly in the energy-dispersive mode (SEM-EDX), has become the method of choice of most forensic facilities for the analysis of GSR. Instead of the traditional light microscope, a beam of electrons is aimed onto the specimen, which interacts with the atoms of the sample. Due to the large atomic mass of lead, antimony, and barium, particles containing these elements give strong, bright images due to backscatter of primary electrons. In addition, low-energy electrons are released from the surface of the specimen; these secondary electrons are important for imaging as they provide useful information concerning the morphology of the sample; in the case of GSR this is highly characteristic (see **Figure 4**). The rapid cooling of gases from high temperatures and pressures results in particles in a range of sizes and shapes from small spheres to irregular flakes, and in trained hands SEM can usually distinguish between environmental contaminants and actual GSR using each particle's size, shape, and morphology.

A major advantage of this method comes from the ability to couple the SEM instrument to an X-ray detector: in the case of SEM-EDX a silicon–lithium semiconductor detector. X-rays are produced when the electrons of the scanning electron microscope strike each GSR particle. Analysis of the X-rays

generated from that particle allows identification and quantitation of individual elements as each element emits a characteristic X-ray spectrum. Fine spheroidal grain particles abundant in antimony, barium, and lead make a strong case that the particle is in fact a GSR. The lead–antimony–barium ratio helps confirm that these elements are detected as a result of the discharge of a firearm rather than as a result of some other environmental means.

This combination of morphological and chemical information for single particles in a nondestructive method makes this approach to GSR analysis unrivalled in its specificity. Due to the obvious power of the technique, it has become widely established in larger forensic facilities and modern instruments have been developed to enable automated GSR particle searches.

### Chromatographic and Other Separation Techniques

Separation techniques such as gas chromatography (GC), high-performance liquid chromatography (HPLC), and capillary electrophoresis (CE) underpin attempts to characterize the organic species in GSR, which arise from partial combustion of the propellant. HPLC has found most application, with electrochemical detection being the most versatile method for the analysis of organic propellant residues. Other detection methods that have been employed for HPLC include mass spectrometry, MS/MS, and fluorimetry (after derivatization with a suitable fluorophore). As the organic constituents in GSR are uncharged, applications of CE to GSR analysis have been in general restricted to micellar electrokinetic capillary chromatography, of which there are a number of reports in the literature.

The use of GC for the analysis of GSR is limited due to the incompatibility of many of the analytes, such as the nitrate esters, and the lack of volatility of nitrocellulose, the major component of smokeless propellant. Despite this, GSR has been successfully analyzed using GC employing a variety of detectors including flame ionization, electron capture, and thermal energy analysis. Thermal energy analysis has been found to be particularly useful as it is selective for the nitro-containing compounds present in GSR. Recent attempts have been made to individualize GSR to a particular class of firearm and/or ammunition using chemometric techniques.

## Hair

**N Watson**, Strathclyde University, Glasgow, UK

© 2005, Elsevier Ltd. All Rights Reserved.

This article is a revision of the previous-edition article by Yoshihiko Fujita, pp. 1655–1661, © 1995, Elsevier Ltd.

## Introduction

Recently, crime has become more vicious and skilful than ever before, so minute substances (trace evidence), which are difficult to hide, are important for the detection of the suspect, especially in cases where he is in contact with the victim or the crime scene. These substances are hair, fibers, soil, etc. Among them hair is noteworthy and can be retrieved easily from the crime scene, because there are ~100 000 hairs on an adult human head and they may be shed one by one every 15 min. The suspect therefore leaves his or her own head or pubic hairs at the crime scene unwittingly. Therefore, hair provides important physical evidence for solving of crime.

Nowadays in the forensic science laboratory, large pieces of human (and animal) hairs collected from the crime scene are examined by morphological methods using macroscope, microscope, and electron microscope, and may be compared with sample hairs of humans associated with the crime. Finally, their origins are determined.

However, it is well known that identification of hair by morphological methods is not always reliable and should be done by a well-trained analyst for maximum reliability. It is difficult to distinguish the suspect's hair from many other hairs left at the crime scene if there is no finding of particular characteristics in the morphology. Therefore, in addition to morphological examination, ABO blood typing from hair can be made, which is helpful in the

comparison of hairs. Furthermore, various instrumental methods for hair analysis have been investigated to obtain more objective information and enhance the degree of certainty in forensic hair comparison. These methods, including a new powerful method (deoxyribonucleic acid (DNA) typing analysis), are introduced in this article together with older ones.

One consequence of the application of DNA testing techniques to hair occurring as evidence has been the reexamination of old cases as the new technologies have become available. In the several instances that have been reported, DNA evidence from hairs has contradicted the interpretations based upon the microscopic examination of crucial hairs used in the original trials. In addition, an American Supreme Court decision in 1993, concerning the grounds of the admissibility of scientific evidence, has resulted in a review of many categories of scientific evidence and their use in the American courts. The reliability of hair evidence has been a cause of particular concern and a number of studies to establish the scientific credentials of such examinations have been published. While these issues are primarily of concern to American practitioners the forensic community in general has benefited from these studies.

Another issue that is continually being addressed is the speed and cost-effectiveness of hair comparisons. To this end the systematic codification of microscopic features in order to generate coded categories of variant forms to improve the consistency of hair examination reporting continues to be developed. Potentially, a count can be made of the different codes reported in a laboratory or system of laboratories to enable a numerical evaluation of the commonness of any given variant form to be estimated. This value would assist the court to assess the significance of evidence.

comparison of hairs. Furthermore, various instrumental methods for hair analysis have been investigated to obtain more objective information and enhance the degree of certainty in forensic hair comparison. These methods, including a new powerful method (deoxyribonucleic acid (DNA) typing analysis), are introduced in this article together with older ones.

One consequence of the application of DNA testing techniques to hair occurring as evidence has been the reexamination of old cases as the new technologies have become available. In the several instances that have been reported, DNA evidence from hairs has contradicted the interpretations based upon the microscopic examination of crucial hairs used in the original trials. In addition, an American Supreme Court decision in 1993, concerning the grounds of the admissibility of scientific evidence, has resulted in a review of many categories of scientific evidence and their use in the American courts. The reliability of hair evidence has been a cause of particular concern and a number of studies to establish the scientific credentials of such examinations have been published. While these issues are primarily of concern to American practitioners the forensic community in general has benefited from these studies.

Another issue that is continually being addressed is the speed and cost-effectiveness of hair comparisons. To this end the systematic codification of microscopic features in order to generate coded categories of variant forms to improve the consistency of hair examination reporting continues to be developed. Potentially, a count can be made of the different codes reported in a laboratory or system of laboratories to enable a numerical evaluation of the commonness of any given variant form to be estimated. This value would assist the court to assess the significance of evidence.

## Structure and Composition of Hair

Hair is an appendage of the mammalian skin produced by an organ known as the hair follicle in the epidermal epithelium. The portion of the hair that lies in the follicle is called the root, whereas the portion above the skin surface is called the shaft. In a cross-sectional view of hair shaft, there is an outer layer of cuticular scales that surrounds the cortex shaft in the center of which a canal-like structure called the medulla is found (Figure 1). Pigment granules (melanin) are dispersed usually in the cortex, produced by melanocytes in the follicle. The hair follicle does not produce hair continuously. Hair grows cyclically, with alternate periods of growth and rest. This cycle is divided into three stages (anagen, catagen, and telogen). In the anagen stage, hair grows on, and in the subsequent catagen stage club hair is formed in the follicle. In the next resting telogen stage, hair ceases to grow. After the inactive telogen stage, the follicle goes into another anagen stage and resumes activity. In man, each follicle has its own growth cycle that is independent of the others. During the growth stage, hair grows at a rate of about one centimeter per month. An adult man has ~100 000 scalp follicles, 90% of which are anagen and 10% telogen.

Chemically, hair is mainly composed of particular proteins (keratins), hard and stable to usual physical and chemical treatment. This characteristic of keratin protein is a result of the high degree of disulfide bonding between polypeptide chains in the molecules. Human hair keratin is composed of 21 amino acids. When these amino acids are grouped together according to functional group, there are high content of hydroxyl, primary amide, and basic amino acid

functions. Human hair keratin is also characterized by high sulfur content due to high cystine content (17–19% residues as half cystine). The remaining constituents are water (*c.* 13% in 65% relative humidity), lipids (originating from the sebaceous gland in the follicle), pigment (principally eumelanins), and trace elements (calcium, magnesium, potassium, zinc, sodium, chlorine, etc., from sweat deposits and extraneous sources).

## Morphological Examination of Hair

At the crime scene, various fibers and hairs are collected by policemen. They are immediately examined at the forensic laboratory in order to identify the suspect and help solve the crime. The examination needs to establish: (1) whether it is a hair or a fiber (synthetic or plant); (2) its species if it is a hair; (3) its somatic origin if it is a human hair; (4) whether it is similar to the suspect or the concerned persons. Microscopic examination will resolve the first point. It will also allow discrimination between human and animal hair, as the medulla of human hair does not develop well and shows less than 0.30 of medullary index (ratio of medulla diameter to hair diameter). But determining the species of animal requires experience in animal hair examination. Almost every animal hair shows specific shape of cuticle and medulla under microscopical observation. With regard to the somatic origin of human hair, there are some basic features that usually indicate the bodily origin of the hair. For example, head hair has long length, 30–120  $\mu\text{m}$  diameter, tapered tip, little diameter variation, various medullation, sometimes cut tips, and treatment. Pubic hair has a twisted

**Figure 1** Microscopic pictures of human hair shed naturally.

form, shorter length, coarse diameter, prominent diameter variation, broad medulla. The morphological association of human hair is carried out by comparing every characteristic of both a suspect's and unknown hair macroscopically and microscopically. The association cannot be done by only one or two characteristics. There are variations within one person from natural growth, but the amount and kind of variation differs between persons. Generally, effective items of macroscopical and microscopical identification of human hair are color, length, diameter, contour, distribution of medulla, and cosmetic treatment. Concerning individuality, there is a limit to the possibility of identifying individual hair among large pieces of hair from many persons by morphological examination.

For some time many forensic laboratories have adopted some form of systematic comparison strategy to improve the consistency of the examinations. One example of this was demonstrated in a study of the efficacy of hair comparisons by microscopic examinations. Fourteen different characteristics were defined as primary and secondary characteristics for comparison. The primary characteristics were the color, cosmetic treatment, texture, pigment distribution, medulla, medullary index (i.e., the width of the medulla as a proportion of the width of the hair), maximum diameter, and presence of cortical fusi (microscopic structures observable within the cortex of the hair). The secondary characteristics were length, cuticular margin, pigment density, pigment size, and shaft diameter variation. By a systematic point-by-point comparison of these characteristics by two examiners working on the same samples in parallel but independently of one another both examiners were able to make correct assignments in a proportion of trials but more importantly did not make any false matches. In other blind trials forensic laboratories could achieve very high rates of correct associations, with no false associations, although some laboratories achieved much poorer success rates. The poorer rates of success have been attributed to the standards of training undergone by the examiners but the studies have provided evidence that, with experienced and well-trained examiners, microscopic hair examination can be a rigorous, truly scientific method of comparison. It is crucial that the hair examiner must be careful that an unwarranted degree of weight is not put on the results.

There are continuing developments of schemes to codify the characteristics by assigning a code to each different alternative form of any given characteristic. Thus, an individual hair specimen may be characterized by a numerical score for each feature defined by the scheme and these can be compiled into an

ordered series. In this way hairs can be categorized and a count made of the number of occurrences of a category in a population. Such a count can be made to generate frequency data so that an examiner could draw upon observational data to give a numerical estimate of the rarity or commonness of any of the defined hair types within a population. An important aspect of such scoring systems is the consistency with which the categories are assigned. However, by the use of photographic standards, termed archetypes, published as an atlas of microscopic features, the form, or variate, of each characteristic observed in the hair considered can be categorized consistently by reference to the archetype.

## Chemical Analysis of Hair Components

### Elements

Chemical features determined by analysis of elements in human hair are helpful for hair comparisons. Analysis of elements in the hair has been accomplished by instrumental methods such as atomic absorption spectrometry, neutron activation analysis, energy dispersive X-ray microanalysis (EDX). Among them, EDX equipped with scanning electron microscopy is widely used in forensic hair examination because it facilitates easy analysis of elements whilst observing the hair structure.

Twenty-seven elements are found in human hairs, and the majority of them are due to an accumulation of products from sweat. These elements can be grouped into two classes: physiological and environmental. The former includes sodium, phosphorus, potassium, and sulfur, which are present at high levels. The latter includes arsenic, cadmium, mercury, and lead, which are called toxic elements. As these elements may indicate some particular environment for an individual, and their amounts vary considerably across individual hairs, they can be specific and effective indications for forensic hair comparison. If a particular element was determined in a suspect's hair, it can be easily compared in sample hairs.

Content of elements in hair is closely concerned with hair color, disease, treatment, sex, and weathering. For instance, the amount of chlorine in male hairs detected by EDX is higher than in female ones among 38 adult persons (Japanese) aged from 20 to 50 years (males:  $0.67 \pm 0.20\%$  w/w; females:  $0.45 \pm 0.12\%$  w/w). Chlorine in hair is considered to come from sweat. Electrothermal atomic absorption spectrometric analysis also shows that calcium is more abundant in permanent waved hair than in untreated hair (waved hair:  $2000\text{--}4500 \mu\text{g g}^{-1}$ ).

Copper content is low in the hair of infantile pellagra (kwashiorkor) and grey hair of an old man, but is high in trichoschisis and black hair. Content of zinc is low in dwarf and blond hair and also in the hair of pregnant women, but is high in ill-nourished children and black hair. Some elements in hair show significant differences of value according to gender and age, as well as various hair treatments. These variations also occur in different scalp areas and different portions of single hair of a man. If there are some patterns of variation in sample hairs found, it may be helpful to compare them with those of suspect's hair.

### Instrumental Analysis

New methods in hair analysis using the many remarkable instruments that have now been developed are described in this section. Human hair (40–80  $\mu\text{g}$ ;  $\sim 1\text{ cm}$ ) can be analyzed by pyrolysis capillary column gas chromatography (Pyr-GC). Some main peaks are observed in the pyrograms of hair samples. Components of these peaks are identified by pyrolysis capillary column gas chromatography-mass spectrometry (PyrGC-MS). Toluene and styrene as pyrolysis products are considered to arise from phenylalanine, phenol and cresol from tyrosine, methanethiol from cystine and/or methionine, and carbon disulfide from cleaving free carboxyl groups and disulfide bridges. It is thought that variation in amino acid composition causes differences in pyrograms of the individual hairs. If reproducibility is established, this method is likely to be used in forensic hair comparison. Hair treatments, especially hair bleaching, were reported to have influenced the chemical and physical nature of hair. Infrared (IR) spectra from a single hair can be measured by Fourier transform infrared analysis for detecting the oxidation of hair. There is an absorbance at  $1042\text{ cm}^{-1}$  not only in bleached hair, but also in permanent waved hair and dyed hair. This absorbance arises from sulfonic groups that result from the cleavage of disulfide bridges in hair. The oxidation occurs more strongly in the hair tip than in the root. This phenomenon also arises from weathering and ultraviolet irradiation. Though it is usually difficult to establish whether a suspect's hair has been treated or weathered from IR spectra, IR analyses can provide evidential clues for hair comparison without consuming the sample. It is possible to investigate differences between chemical oxidation of a disulfide bond and weather-beaten oxidation in a single hair by electron spectroscopy for chemical analysis, because the bonding energy of sulfur atoms differs under the various conditions. A method of dating samples by electron spin resonance (ESR) spectroscopy has been

developed and applied to a wide variety of materials. Red melanin (phaeomelanin), which does not have unpaired electrons, and black melanin (eumelanin), which has unpaired electrons, show different spectra; thus, the intensity of the ESR signal of brown hair is weaker than that of black hair. The ESR signal of cut hair reduces according to the time since cutting. As the radical in the hair of 1 cm long can be detected by ESR analysis, this method will be applied to the field of forensic science. Derivatives such as amino-hydroxyphenylalanine and pyrrole-2,3,5-tricarboxylic acid, respectively, produced from phaeomelanin and eumelanin in human hair ( $\sim 4\text{ mg}$ ) are determined by liquid chromatography (LC). The contents of both melanins can be determined using LC and provide a clue for hair identification.

## Biochemical Analysis of Hair

### Intracellular Enzymes of Hair Root

It has become clear that many intracellular enzymes exist in the root sheath of human hair. They are alcohol dehydrogenase (ADH), esterase D (EsD),  $\alpha$ -L-fucosidase (FUC), glucose-6-phosphate dehydrogenase (G6PD), 6-phosphogluconate dehydrogenase (6PGD), phosphoglucomutase (PGM), etc. The biochemical properties of these enzymes in hair root are very similar to those in other tissue cells. Some of these enzymes have different proteins with similar enzymatic activity. They are called isoenzymes. These isoenzymes show 3–10 phenotypes. PGM<sub>1</sub> isoenzyme is frequently utilized for forensic hair identification, because it shows more phenotypes than other isoenzymes (Table 1). Many isoenzymes are detected by means of isoelectric focusing with polyacrylamide gel having a high separating ability. Therefore, polymorphism of these enzymes can be one item of information like ABO blood groups for hair identification if the activity of the hair root enzyme is observed.

### Electrophoresis of Hair Keratin Protein

Forensic hair identification has been investigated using the electrophoretic patterns of hair keratin

**Table 1** Representative isoenzymes in human hair root

<i>Isoenzyme system</i>	<i>Numbers of phenotype</i>	<i>Methods of electrophoresis</i>
ADH	3	Isoelectric focusing
EsD	3	Isoelectric focusing
FUC	3	Isoelectric focusing

6PGD	3	Starch gel
PGM <sub>1</sub>	10	Isoelectric focusing

protein, which have a variety of composed peptides and a genetic polymorphism. Hair keratin, a polymer of amino acids, has a firm structure and is not dissolved in water, common buffers, or organic solvent. In order to solubilize hair keratin, the bridge linkage of disulfide bond is cleaved by reductant (e.g., 2-mercaptoethanol), and sulfhydryl groups produced by the reduction are alkylated by iodoacetate for the purpose of preventing reoxidation. As a result of that, a soluble derivative of *S*-carboxymethylkeratin corresponding to native protein in hair is obtained, and becomes a more soluble substance suited for electrophoresis by adding urea (protein-denaturing reagent).

Keratin proteins in human hair are composed of low-sulfur proteins (mol. wt.  $\sim 50\,000$ – $76\,000$ ) of cortical fibrils and high-sulfur proteins (mol. wt.  $\sim 25\,000$ – $43\,000$ ) of matrix among fibrils. Phenotype frequency of low-sulfur protein variant is  $\sim 4\%$  in Caucasian hairs detected by 10% polyacrylamide gel electrophoresis, but its variants have not been detected in Mongoloid (Japanese) hair. On the other hand, high-sulfur protein variants have been detected in  $\sim 30\%$  of Japanese. These variants are considered to be inherited in autosomal dominant fashion. Furthermore, a two-dimensional electrophoresis system has been developed for obtaining detailed information of these hair proteins. More different patterns can be observed by this analysis than by the one-dimensional system, and are said to arise from nutritional, physical, and environmental factors and disease in individuals. For example, a two-dimensional system using acidic (pH 3) polyacrylamide gel–sodium dodecyl sulfate provides eight variable protein groups or spots, in which some additional spots or their absence are related to those factors. These electrophoretic analyses of hair proteins are also effective in the identification of animal species.

### Amino Acids

Remarkable amino acid analyzers have been developed and can analyze one piece of hair. Variation of amino acid composition in human hair is caused by nutrition, disease, and treatments (permanent waving, bleaching etc.). The effect of cosmetic treatments such as bleaching, dyeing, or permanent waving on the amino acid composition is to decrease the content of cystine and increase the competent of cystic acid depending on the extent of the treatment. Thioacetylated lysine, carboxymethylthiol cystine, dithiodiglycolic acid, and methionine sulfone have been found in permanent waved hair. This information on variation in amino acid analysis of a single hair may be helpful for forensic hair comparison.

### DNA Analysis

DNA fingerprinting was developed for individualization system in 1985. Analyses using DNA profiling with variable numbers of tandem repeat polymorphism has been carried out for identification of forensic samples such as bloodstains and sectional stains. Concerning forensic hairs, several DNA analyses of hair root sheath cells have been reported. However, DNA analysis of a hair shaft has not succeeded to date, because DNA recovery from a hair shaft is in order of tens of picograms and only low molecular weight DNA (below 200 base pairs (bp)) is left in the hair shaft. Recently, microsatellite DNA polymorphism has been detected by the polymerase chain reaction technique. This polymorphism can be applied to DNA analysis of hair shaft. If DNA analysis is combined with microscopic and instrumental analysis in forensic examination, hair individualization can be more accurate.

### Mitochondrial DNA Analysis

Human identification by testing the nuclear DNA within cells has become a powerful and sensitive tool. It can be used with those hairs that possess some tissue, usually in the form of cells from the hair root or from sheath cells that adheres to forcibly removed anagen hairs. The presence of these tissues often requires microscopy to find them and in some instances a result can be obtained from the hair shaft. However, in many instances such tissue is not present, such as the case of telogen hairs that have been shed naturally, and there is insufficient material for tests of nuclear DNA to be productive. An alternative strategy is to test the DNA content of cell organelles called mitochondria. These are present in the cytoplasm of the cells and take part in the cellular respiratory mechanisms to provide energy for cellular processes. They are present in high numbers within the cells in tissues that are dividing rapidly. Each particle contains multiple copies of the mitochondrial DNA, or mtDNA, with the result that the copy number of the mtDNA can be several thousand-fold greater than the nuclear DNA.

The dermal material in the hair root where the hair shaft is produced is an example of such tissue. As the shaft is created and subsequently keratinized the mitochondrial particles are trapped in the shaft and persist in the hair. The mtDNA thus presents a more promising target for DNA testing and indeed the exploitation of this feature of hair has become an important part of forensic hair analysis.

### Haplotypes and Databases of mtDNA

The mtDNA genome occurs as a single, double-stranded, DNA loop. The bases making the loop are

numbered one to 16569, representing the entire loop. Two parts of the loop have been found to possess greater variety in the DNA base sequence than the rest of the loop. These two regions are called hypervariable regions I and II or HVRI and HVRII, respectively. The mtDNA sequence has been entirely determined and a widely recognized reference sequence, such the Cambridge Reference Sequence (CRS), can be used as a standard against which the sequence of any portion of the mtDNA of a sample is compared. There is no opportunity for recombination of the base sequences present on the mtDNA loop from generation to generation but mutations do occur within the mtDNA, especially within the hypervariable regions, so that the base sequence changes at certain sites. These changes can be in the form of transitions, transversions, or insertions or deletions. A transition is a change of one purine to another purine, for example, an adenine base changed to a guanine, or a pyrimidine changed to another pyrimidine, e.g., a cytosine to a thymidine. A transversion is a change of a purine to a pyrimidine, or a pyrimidine to purine. Insertions or deletions of base sequences are called indels. The mtDNA loop hypervariable regions HVRI and HVRII are rich these variations. Many forensic laboratories typically sequence positions corresponding to the HVRI and HVRII regions.

A nomenclature system has been developed for mtDNA typing. It has been adopted as a convention within various bodies of the forensic science community. Simply put the rules are that the bases determined from a sample of mtDNA are compared to that of a reference sequence, for example, the CRS, at corresponding base positions. Where transitions or transversions have occurred, the change is denoted using the mtDNA base position number followed by the initial letter of the base found in the sample at that position. Only those positions that differ from the reference sequence are stated. The CRS is based upon a human mtDNA sequence that has been found subsequently to possess uncommon base types at certain positions. For example, a specific position of the CRS may be an A while most people possess a G at that position. Therefore, many sample mtDNA determinations, should they include this position, will include the recorded variation of a G at that position because it differs from the reference sequence. Where there is concordance between the sample bases at a given position with those of the reference sequence then there will be no specific designation on the assumption that the base type of the sample is the same as reference sequence.

Indels are denoted by citing the base position at the 5' side of the indel and using a decimal point to

indicate an insertion; for example, specifying the base type as a capital letter of the base name following the position number, 85.1C or 85.1A. Where there is a mixture or an ambiguity then the letter N is used; however, the International Union of Pure and Applied Chemistry letter convention can be used. In the case of deletions again the 5' base position number is used, followed by the letter d; so, for example, a deletion might be denoted '85d'.

### Mitochondrial DNA Sequence Alignment

The comparison of sequence data with a reference sequence requires careful attention to sequence alignment due to the possibility of discrepancies between sequences of the samples and that of the reference sequence arising from indels. The convention for aligning sequences for comparison is given here in general terms but there are a number of special circumstances that are dealt with more thoroughly in the literature. The conventions propose that sequences should be aligned so as to minimize the number of differences between the sample sequence and the reference sequence. In cases where there are equally good alternative means of aligning the sequences the priorities should be to align by the indels first so that the displacement of portions of the sequence arising from deletions or insertions are allowed for, after which come translations and then transversions.

Once the alignment has been made the combination of variations occurring at different places on the mtDNA strand can be identified and sequences can be compared with the reference sequence and cross-comparisons between different hair samples made. In Caucasians, there appear to be an average of around eight positions within the HVRs where the nucleotides differ between unrelated people and around 15 differences between people of African descent. As there is no recombination of the mtDNA the combination of variations in the HVRs is inherited as a single entity called a haplotype. The mitochondrial databases therefore count the frequency of the different haplotypes.

The HVR regions possess the greatest number of variable sites in the mtDNA and the base sequence of the variable regions, or the major parts of them, of the questioned hair are compared to the corresponding sequences determined from the reference hairs. Although there may be potentially many different haplotypes the maternal inheritance of the mitochondrial genome will restrict the diversity observed in a population, as many individuals will possess co-ancestry by the maternal line. Nonetheless, in studies carried out of the haplotypes observed in different populations the number cooccurring in different

individuals is small. As databases grow and more mtDNA sequences are determined there will be continual adjustments to the frequencies observed for different haplotypes. Population databases consisting of the sequences from the mtDNA from unrelated individuals of different populations have been established.

Certain haplotypes share a high proportion of the types of nucleotides found at the variable sites. Phylogenetic studies can be used to identify groups of haplotypes that show a high degree of commonality. Such groupings are termed haplogroups and in Caucasians it has been found that 10 haplogroups account for 99% of the population and 90% of this proportion of the population are represented by five haplogroups.

### Heteroplasmy

The sperm head possesses no mitochondria and upon fertilization only the contents of the sperm head enter the egg cell. A consequence of this is that, in principal, at least, no paternal mtDNA is passed to the fertilized cell and only the maternal mtDNA is transmitted to the next generation so that in theory all the mtDNA sequences in a person should be the same, i.e., homoplasmy. However, in practice different populations of mtDNA may coexist within one person, i.e., heteroplasmy. In the course of embryonic development the number of mtDNA molecules is greatly reduced, perhaps to less than 10, so that the chance of a variant mtDNA haplotype, present in the original pool in only a small proportion of the total mtDNA, being passed on is reduced. This therefore acts as a brake, or bottleneck, on the accumulation of heteroplasmic variations in the pool of mtDNA types. As the reductive process does not select for particular mtDNA haplotypes heteroplasmic variants may be missing from some cells after the bottleneck. If different variants were present in the original pool then some cells may possess one type of variant and others a different variant. In most tissues there will be a mixture of mtDNA from different cells so that an analysis of the mtDNA haplotypes will reflect the heteroplasmic mixture if any is present. It is possible that one haplotype predominates to the extent that a different haplotype present may not be detectable but this is a separate issue. However, the analysis of the mtDNA from the shaft of a single hair in a forensic context may not represent a sampling of the different heteroplasmic haplotypes present in the donor.

The hair shaft is produced from a collection of rapidly dividing cells in the hair bulb matrix of germinal cells. These cells divide rapidly and contain many mitochondria. The new cells produced do not

divide again but swiftly differentiate into cuticle cells, cortical cells, and medullary cells. One member population of the germinal cell matrix is the melanocytes. These are pigmented cells that produce melanin and store it in melanosomes. These cells produce the pigment granules that give the color to the hair and have large energy requirements.

The melanocytes come from the neural crest, a group of cells in the neural tube of embryo. These cells move out to different places in the embryo to develop into a variety of types of adult cells. The melanocytes are distributed throughout the skin at random and constitute a different population of cells from the rest. They become a part of the germinal cell matrix.

The melanocytes divide slowly, unlike the other cells of the germinal matrix of the root bulb, but they produce dendritic arms that are assimilated by endocytosis into the precortical cells that are moving out of the germinal matrix. These precortical cells are undergoing keratinization as a part of the process of the formation of the cortex of the hair and that involves the intensive production of keratin protein filaments. Therefore, there are two sources of the mtDNA molecules present in the cortex of the hair, one from the germinal cells of the matrix of the root bulb and the other from the melanocytes. The proportions of each contribution of mtDNA molecules are not known; however, there will be very little opportunity for daughter mtDNA molecules to be produced in the differentiating cortical cells while the melanocytes are continuously producing more pigment and mitochondria. Consequently, there can be genetic drift in the proportions of mtDNA molecules from the two sources so that haplotypes of mtDNA observed along the shaft of the hair can be different in different places. Also, different hairs that have come from the same follicle can potentially have different haplotypes. Therefore, while mtDNA analysis is undoubtedly a powerful tool for the forensic analyst there are special considerations that have to be taken into account in any interpretation made.

Opinions have been expressed that microscopic examination of hairs should be regarded as a presumptive step to act as a screening procedure prior to mtDNA analysis. However, many reports also emphasize the importance of the combination of the two approaches because the contribution the microscopic comparison can make. The microscopic examination gives an independent comparison of different characteristics. The analysis of mtDNA remains an expensive procedure, and not all hair specimens yield a usable result. Microscopic examination can eliminate obvious mismatches such as many nonhuman hairs, it can be used on fragments

possibly too small for DNA testing, and it can yield other information such as an association with racial, Caucasian/European, African, or Asian, ancestries. It is necessary to use microscopic examination to obtain information about the possible body areas and it can also yield other information such as cosmetic treatment. The microscopist can also identify if cellular tissue is adhering to the hair. This is a potential source of material for DNA testing using the same system of combined tests of independent short tandem repeats, or multiplex STR analysis, as used with other biological materials. This test can produce very powerful evidence of association between a hair and a donor if there is a match of DNA types.

### Immunological Analysis of Hair

Keratin proteins and blood group substances such as antigens are identified in human hair, whereas immunoglobulin has not been detected in it. Blood group substances (A, B, and H) are contained mainly in the hair cortex. These substances have the chemical property of glycolipids. An absorption-elution technique for determination of ABO blood group from forensic hair sample has been developed. Using this technique it is possible to determine the ABO blood group from one single hair ~6 cm in length. Furthermore, the unlabelled antibody immunoperoxidase (peroxidase-antiperoxidase) method is utilized for determining the blood group of more

minute hair. The ABO blood grouping is used for discrimination in forensic hair comparison, especially when the analyst cannot distinguish the suspect's hair from the control sample hair with similar morphological features.

### Chemical Analysis of Components Remaining on or in Hair: Hair Shampoo, Hair Care Products, and Oxidative Dyes

People use hair shampoo, hair rinse, hair care products, and coloring preparations regularly for the purpose of hair beauty, and seldom change the brands of these products. Therefore, forensic hair identification becomes easier if these components remaining on or in human hair can be detected. The main components of hair shampoo are anionic (for instance, lauryl sulfate triethanolamine, sodium lauryl sulfate) or nonionic substances. Other components are amphoteric detergent, conditioner, agents increasing viscosity or foaming, dye, and perfume. Shampoo components remaining in 5–10 cm long hair are extracted with a solvent of acetonitrile and water, and these extracts are analyzed by LC. The liquid chromatograms for four individuals shown in **Figure 2** are different from each other. Because quantitative ratios of various components of shampoo products differ from ones of the hair's extracts, it is difficult to identify the brand of shampoo used. But LC

**Figure 2** Liquid chromatograms of hair extracts from four different persons. Extracting solvent: acetonitrile and water (70:30, v:v); equipment Varian model 5000 liquid chromatograph with Waters Associates fixed-wavelength absorbance detector (model 440) operating at 254 nm; column: 20 cm, 5  $\mu$ m Nucleosil C-18, 4.6 mm i.d. (Skandinaviska Gene Tec AB); mobile phase: acetonitrile and water (50:50); flow rate: 1.5 ml min<sup>-1</sup>. (Reproduced with permission from Andrasko J and Stocklassa B (1987). HPLC analysis of shampoo residues in human head hair. *Proceedings of the Eleventh Meeting of the International Association of Forensic Science*, vol. 20, pp. 249–255.)

nondestructive analysis can give more objective and helpful information in individualizing of target hair among forensic hair samples. Identification of the brand of hair care products (men's and women's hair care products, oxidative dyes, hair sprays, and hair growth promoters) by components remaining on or in human hair is investigated. These components are identified mainly by GC, GC-MS, and thin-layer chromatography (TLC) analysis after extraction with ether or methanol. The main components of men's hair care products (hair liquids) remaining on human hair are identified as 2-hexyldecanol (emollient), isopropyl myristate (emollient), diethyl phthalate (perfume reserver), benzyl benzoate (perfume), methyl dihydrojasmonate (perfume), pentapropylene glycol (moisturizer), oxybenzone (sunscreen), etc. In the experiments, hair liquids of 57 brands produced by 17 companies are grouped into 21 classes on the basis of main components remaining on human hair, and among them hair liquids of 11 brands are identified by particular components (docosamethyldecasiloxane (polisher), isostearyl alcohol (emollient), diisopropyl sebacate (emollient), benzyl salicylate (sunscreen, perfume reserver), etc.). The major components of hair liquids remaining on human hair can be detected as long as 5 days after treatment. Other hair care products are also grouped similarly.

In the application of this method to an actual crime involving injury, components of hair care products remaining on hair adhering to a suspect's clothing were analyzed by GC and GC-MS, since morphological investigation had shown that some of these hairs were different from the victim's head hairs. The five main components remaining on hairs from both the victim and the suspect's clothing was found to be exactly the same. These gas chromatograms are shown in Figure 3. Two of these components were identified as dibutyl phthalate (perfume reserver or emollient) of peak 1 and the unidentified component of peak 4 originated from hair sprays which the victim used.

Hair coloring preparations are classified into four types: temporary dye, metallic (progressive) dye, ionic (acidic and basic) dye, and permanent (oxidative) dye. The oxidative dye is the most popular hair dye because of its color durability and easy application. Oxidative dyes are usually composed of dye compounds (A) solution and a hydrogen peroxide (B) solution. Both solutions are creamy. The A solution also contains strong alkaline ammonia to open hair cuticles. Dye components polymerize into indophenol-like trimers, etc., in the presence of hydrogen peroxide, primarily in the cortex of the hair. Hairs 3 cm long dyed by oxidative dyes of 34 brands are dissolved in the solution of methanol plus  $3 \text{ mol l}^{-1}$

**Figure 3** Gas chromatograms of components remaining on human hair adhering to suspect's clothing (A) and victim's head hair (B). Equipment: Shimadzu GC-4CM with a flame ionization detector column: 3 mm i.d.  $\times$  2 m, 1% Silicone OV-17 on Chromosorb-W (AW-DMCS, 80–100 mesh); column temperature: program from 100 to 280°C at 5°C min<sup>-1</sup>; carrier gas: nitrogen, 40 ml min<sup>-1</sup>.

**Figure 4** Thin layer chromatograms of oxidative dyes remaining in human hair. Capital letters (A–H) are assigned to indicate the companies of dye products. Numbers (1–6) indicate brands of products. TLC plate: Silica-gel 60 (20  $\times$  20 cm, 0.25 mm thickness, purchased from Merck Co.); developing solvent chloroform–ethyl acetate–methanol (6:3.5:0.5, v/v).

sodium hydroxide and sodium hydrosulfite dithionite), and these methanol extracts are analyzed by TLC. As shown in Figure 4, detectable amounts are present in hair dyed by 16 brands. These brands are classified into three groups from the identified components; i.e., in the first group only *p*-phenylenediamine (PPDA) is detected, the second group only 2,5-diaminotoluene sulfate and the third group PPDA and an unidentified compound that may be formed in the dyeing process are detected. Furthermore, after neutralization of the alkaline solution with  $3 \text{ mol l}^{-1}$  acetic acid, it is extracted with ether. From the extracts, other dye components, *o*-, *m*-, and *p*-aminophenols are identified by GC-MS after trifluoroacetylation. The identification of brands of oxidative dyes used has been no more successful than that of brands of shampoos used. But it is possible in

some cases to ascertain whether target hair is dyed or not by analysis of remaining components of hair coloring preparation.

## Drugs

If amphetamines are detected in a suspect's head hairs, the suspect may be arrested under stimulant control law and the hairs can be used as evidence in a trial. Furthermore, various drugs contained in human hairs not only provide evidence of crime under drug control laws but also important clues to hair comparison for other criminal investigations. Many cases of drug abuse have been established by using human hair. These drugs are stimulants (amphetamines), heroin, phencyclidine, cocaine, barbiturates, etc.

It is generally thought that blood capillaries break in bulb of hair root and drugs are taken into the hair while matrix cells produced in hair papilla grow and are keratinized. The drugs are contained mainly in hair cortex and amount to 50–100 ng mg<sup>-1</sup> single hair (equivalent to ~10 cm long). The drugs can be detected by radioimmunoassay and GC–MS. In the GC–MS analysis of amphetamines in human hairs, sample hairs of 10 mg are washed with 0.1% sodium lauryl sulfate and water three times under supersonication, and are dried. These hairs are dipped in the solvent mixture (2 ml) of methanol and 5 mol l<sup>-1</sup> hydrochloric acid (20:1) under supersonication. Then it is left to stand overnight at ambient temperature. The solvent mixture is separated, and is dried under a stream of nitrogen. The resulting residues are dissolved in the solvent mixture (200 µl) of trifluoroacetic anhydride and ethyl acetate (1:1), and are heated at 55°C for 20 min. The reaction mixture is dried under a stream of nitrogen. The residue

**Figure 5** Mass spectrum of trifluoroacetyl derivative of methamphetamine extracted from suspect's head hairs. Sample hairs: 100 pieces of 1 cm long hair; extracting solvent of hairs: methanol–5 mol l<sup>-1</sup> hydrochloric acid (20:1); equipment Shimadzu GCMS-OP 1100EX; column: Shimadzu capillary column HiCap-CBP10-W25-100, 0.53 mm i.d. × 25 m cyanopropyl (thickness 1.0 µm); column temperature: 140°C; carrier gas: helium 20 ml min<sup>-1</sup>; ion source temperature: 270°C; electron energy: 20/70 eV.

dissolved in ethyl acetate is subjected to GC–MS analysis. A mass spectrum of trifluoroacetyl derivative of methamphetamine extracted with methanol from suspect's hairs in a stimulant offences case is shown in Figure 5.

Compared with urine, hair samples have many advantages as an evidential material, because of easy sampling and handling, long stability time (approximately 3 days–1 year after intake), and high sensitivity (detectable at the nanogram per milligram level). Moreover, an individual history of drug intake can be worked out by analyzing each segment along the hair shaft from hair root to hair tip.

### Introduction – Types of Drugs

Drugs of abuse can be divided into different types according to their method of production or isolation. Natural drugs are active constituents and/or secondary metabolic products, of plants and other living systems, which are isolated by some method of extraction. Morphine is one such example. Semisynthetic drugs are products from natural sources, which have undergone some chemical refinement such as diamorphine, which is the diacetylated reaction product of morphine. Synthetic drugs are artificially produced substances for the illicit market, which are almost wholly manufactured from chemical compounds in illicit laboratories (for example amphetamine). Some forms of synthetic drugs are also called designer drugs and are substances whose molecular structure has been modified from the original in order to optimize their effect on the one hand and bypass laws and regulations governing the control of substances on the other.

### Natural and Semisynthetic Drugs

#### Opiates

Opium is a natural product obtained from unripe poppy capsules. There are over 100 species of the genus *Papaver* (or poppy) known, however only two, *Papaver somniferum* and *Papaver setigerum* D.C., are the main plants cultivated in the production of opium.

An incision is made in the poppy capsule and the latex, which oozes from the incision, is scraped off and collected to produce a raw opium gum. When fresh, the material is a sticky tar like brown substance

with a liquorice like odor which becomes brittle as it dries. Raw opium is also obtained from poppy straw. Opium is a complex mixture containing sugars, proteins, lipids, and water as well as the active alkaloid compounds (10–20%). About 40 alkaloids are known and fall broadly into two categories:

- Phenanthrene alkaloids such as morphine, codeine, and thebaine.
- Isoquinoline alkaloids such as papaverine and noscapine.

The relative amounts of these alkaloids varies and is dependent on factors such as climate, soil fertility, altitude, available moisture, and age of the plant. Raw opium can be used for smoking but must first be extracted most commonly with water. Morphine can still be detected in the left over dross that remains in the opium pipe.

**Morphine production** Several purification processes can be used in the preparation of crude morphine from raw opium, two of which are highlighted below. Not all production laboratories may use these methods.

1. The lime method involves the addition of calcium hydroxide (lime) to opium in water. This completely extracts morphine and codeine and partially extracts thebaine and papaverine. Ammonium chloride, alcohol, and ether are added and the solution filtered. Morphine precipitates while thebaine and papaverine remain in the ether layer. The crude morphine is purified by refluxing in dilute sulfuric acid in the presence of charcoal. The final morphine base is precipitated as an off white material by addition of ammonium hydroxide.

2. Raw opium is dissolved in water and the pH adjusted to 6.5 to precipitate noscapine and papaverine, which is removed. The solution is then made alkaline to precipitate morphine and extracted

### Introduction – Types of Drugs

Drugs of abuse can be divided into different types according to their method of production or isolation. Natural drugs are active constituents and/or secondary metabolic products, of plants and other living systems, which are isolated by some method of extraction. Morphine is one such example. Semisynthetic drugs are products from natural sources, which have undergone some chemical refinement such as diamorphine, which is the diacetylated reaction product of morphine. Synthetic drugs are artificially produced substances for the illicit market, which are almost wholly manufactured from chemical compounds in illicit laboratories (for example amphetamine). Some forms of synthetic drugs are also called designer drugs and are substances whose molecular structure has been modified from the original in order to optimize their effect on the one hand and bypass laws and regulations governing the control of substances on the other.

### Natural and Semisynthetic Drugs

#### Opiates

Opium is a natural product obtained from unripe poppy capsules. There are over 100 species of the genus *Papaver* (or poppy) known, however only two, *Papaver somniferum* and *Papaver setigerum* D.C., are the main plants cultivated in the production of opium.

An incision is made in the poppy capsule and the latex, which oozes from the incision, is scraped off and collected to produce a raw opium gum. When fresh, the material is a sticky tar like brown substance

with a liquorice like odor which becomes brittle as it dries. Raw opium is also obtained from poppy straw. Opium is a complex mixture containing sugars, proteins, lipids, and water as well as the active alkaloid compounds (10–20%). About 40 alkaloids are known and fall broadly into two categories:

- Phenanthrene alkaloids such as morphine, codeine, and thebaine.
- Isoquinoline alkaloids such as papaverine and noscapine.

The relative amounts of these alkaloids varies and is dependent on factors such as climate, soil fertility, altitude, available moisture, and age of the plant. Raw opium can be used for smoking but must first be extracted most commonly with water. Morphine can still be detected in the left over dross that remains in the opium pipe.

**Morphine production** Several purification processes can be used in the preparation of crude morphine from raw opium, two of which are highlighted below. Not all production laboratories may use these methods.

1. The lime method involves the addition of calcium hydroxide (lime) to opium in water. This completely extracts morphine and codeine and partially extracts thebaine and papaverine. Ammonium chloride, alcohol, and ether are added and the solution filtered. Morphine precipitates while thebaine and papaverine remain in the ether layer. The crude morphine is purified by refluxing in dilute sulfuric acid in the presence of charcoal. The final morphine base is precipitated as an off white material by addition of ammonium hydroxide.

2. Raw opium is dissolved in water and the pH adjusted to 6.5 to precipitate noscapine and papaverine, which is removed. The solution is then made alkaline to precipitate morphine and extracted

with an organic solvent (such as ether) to remove thebaine and codeine.

**Heroin production** Morphine free base is refluxed in acetic anhydride for ~5 h. The mixture is allowed to cool and is neutralized with sodium carbonate causing the precipitation of crude diacetylmorphine free base, the illicit drug in heroin samples. Monoacetylation of morphine and acetylation of any codeine present also occurs. The crude product is purified by dissolving in acidified water containing charcoal and the free base precipitated by the addition of sodium carbonate. If the hydrochloride salt is required the free base is dissolved in acetone and the product precipitated by the addition of hydrochloride acid.

Because of the nature of the raw opium starting material, the production process, and the addition of excipients to produce 'street' heroin samples, there can be a considerable intersample variation (Figure 1).

**Worldwide heroin production** Southwest and Southeast Asia are the principal regions of illicit poppy cultivation, despite eradication and crop substitution programs carried out in these regions. In Southwest Asia, the main area of production is along the borders of Afghanistan and Pakistan in an area known as the Golden Crescent. In Southeast Asia, Myanmar is the major opium producing country. This area is known as the Golden Triangle (where Myanmar, Thailand, and Laos join). In the western hemisphere, Mexico and Colombia are the principal producers of opium. Enormous quantities of morphine base, produced in laboratories in the Helmand province of Afghanistan, are also transported overland through Iran to Turkey for conversion into diamorphine and heroin.

**Traffickers** Heroin is frequently trafficked through Asian airports like Bangkok, Mumbai, Delhi, Tehran, Karachi, Islamabad, and Lahore to smuggle heroin in body cavities or household goods. European nationals are recruited as couriers to bring heroin by

air from Southeast Asia to Europe. Moscow has developed into a hub of activity and from there trafficking is organized in Ukraine, Romania, and some Central Asian Republics. Heroin is also trafficked from Pakistan and Thailand by mailing parcels usually by express mail services to various destinations in North America and Europe. The drug is also smuggled from Turkey to Greece and into other European countries.

**Heroin trafficking in the USA and Australia** For a number of years, heroin in the USA arrived mainly from Southeast Asian countries, which had well-knit networks in the USA. Australia and North America are identified as two of the major international heroin markets for Golden Triangle heroin as well as the East and Southeast Asian countries. In Australia, the drug is mainly transported by boat from Ho Chi Minh city in Vietnam. Most of the heroin is imported into Sydney for distribution to the rest of Australia by road.

**Heroin trafficking in the European Union** The Central Asian Republics (Kazakhstan, Uzbekistan, Kyrgyzstan, Turkmenistan, and Tajikistan) are becoming a focal point for opium and heroin traffic from Afghanistan bound for Russia and Western Europe (Balkan route or Silk route). More than 65% of the Afghan opiates are exported via these countries. Small quantities of heroin are smuggled frequently by land vehicles principally train, bus, and truck. Since 1998, airlines are also being exploited by the trafficking organizations. Female couriers are frequently recruited for trafficking, concealing heroin in baggage or within their bodies. Moscow and other Russian cities are the usual rail and air destinations of this traffic. Heroin is further trafficked to the West European countries from Russia.

The organization of heroin traffic in Europe is controlled by Turkish and Albanian criminal syndicates. The latter were particularly active in Switzerland, Norway, Sweden, and Balkan countries. From Eastern Europe heroin is mainly distributed to Belgium, the Netherlands, Iberia, and the UK in routes controlled by Turkish criminal organizations, or to Denmark, Germany, Austria, and Scandinavia in routes controlled by Albanian and Yugoslav criminal organizations.

### Cocaine

Cocaine is derived from ecgonine alkaloids in the leaf of the Coca (*Erythroxylon* species) plant. There are various varieties of plant, which produce leaves of different size and appearance. In all species the upper

**Figure 1** Morphine and heroin.

side of the leaf is darker in color. The underside of the leaf has two lines running parallel to the midrib of the leaf and are considered characteristic of the Coca leaf.

**Coca paste production** Coca leaves are mixed with calcium hydroxide (lime) and water. The mixture is crushed and stirred in a hydrocarbon solvent, usually kerosene. The extracted coca leaf residue is removed and the kerosene extracted with acidified water. The cocaine alkaloids are extracted into the aqueous layer and coca paste is precipitated by the addition of base. This paste contains crude cocaine as well as a mixture of inorganic salts. Alternatively, the leaves can be crushed in dilute sulfuric acid, extracted with kerosene, and the aqueous layer made alkaline with ammonia or a similar method to precipitate the alkaloids.

**Cocaine production** Coca paste is dissolved in sulfuric acid to hydrolyze the alkaloids and produce ecognine. This is treated with 10% boron trichloride to produce ecognine methyl ester. Potassium permanganate is also added until the solution turns and remains pink. This removes cinnamoylcocaine isomers, which may be present in the mixture. The mixture is filtered, and the addition of base to the filtrate precipitates cocaine free base known as 'crack' cocaine. The free base is dissolved in ether and precipitated as the hydrochloride salt through the addition of hydrochloric acid and is called 'snow' cocaine.

No two illicit samples of cocaine will be exactly the same though the variation from sample to sample is much less than for heroin. In most cases the drug appears as a fine white powder. Most cocaine, which is trafficked, contains ~30% cocaine hydrochloride with other substances such as lidocaine, procaine, or benzocaine added and the sample bulked with lactose, sucrose, or manose. In some circumstances cocaine is present as large white crystals and known as rock cocaine (Figure 2).

**Worldwide cocaine production** The major producers of cocaine are Bolivia, Columbia, and Peru, which produce ~700 tons of cocaine per annum. Of this, approximately 40 tons is destined for the European market and the remainder trafficked to the USA. The results of eradication programs and aggressive antinarcotics policies in Colombia, Peru, and Bolivia have caused growers and traffickers to search for new cultivation areas and transportation routes in the region. Traffickers are also using advanced technology to obtain better yields with each harvest; studying new methods to side step the governmental

**Figure 2** Cocaine.

measures such as neutralizing the effects of aerial spraying, and recycling chemical precursors which are becoming more difficult to obtain due to the stricter importation/exportation controls.

**Trafficking** Criminal groups operating from South America smuggle cocaine and heroin into North America, principally using land routes through Mexico, sea routes through the Caribbean corridor, and international flights. Although traffickers operating from Colombia control wholesale cocaine distribution throughout the heavily populated Northeastern United States, traffickers operating from Mexico control wholesale cocaine distribution throughout the West and Midwest of the country.

Africa continues to be an important transit point for cocaine from South America destined for domestic consumption and to European countries, mainly by use of the postal services, but also increasingly by sea containers. Nigerian criminal organizations operate widely in the African continent and they control the Sub-Saharan drug markets. Northern Africa is also used as a transshipment point for cocaine entering Europe and some evidence shows direct connections between local European drug traffickers and South American cocaine gangs. Cocaine has not yet made great inroads in Southwest and Southeast Asia markets. But increases in tourism and international trade, and the corresponding growth of air and shipping traffic contribute to the smuggling of small quantities of cocaine for domestic consumption.

**Cocaine trafficking in the European Union** Trafficking organizations target countries in Eastern and Southern Europe as intermediary stopovers for both sea and air freight consignments filled with large quantities of cocaine, which were ultimately destined to Western Europe. Analysis suggests an increasing presence of transnational criminal groups controlling

each step in the cocaine trafficking, such as Nigerian and Albanian trafficking organizations, which are becoming increasingly active in the importation and distribution of cocaine in Europe. Cocaine is smuggled both by sea and air in cruise liners, yachts, fishing boats, recreational vessels, and small planes specially adapted for drug smuggling. Most cocaine is transported to the European Union (EU) from Columbia via the Caribbean, Suriname, and into Belgium, France, the Netherlands and the Iberian Peninsula often along old historical trading routes. Other routes include importation through the Balkans and Eastern Europe. Chemicals used in the processing of cocaine are transported by European crime groups back to Columbia via these same routes.

### Cannabis

The botanical name of cannabis is *Cannabis sativa* and it is often referred to as marijuana or grass (herbal cannabis) and hashish or hash (cannabis resin), terms associated with cannabis grown for its illicit use, or as hemp, a term usually associated with cannabis plants grown for their fiber content.

Cannabis is native to the mountainous areas of Central and South Asia and the plant has been used by man for over 6000 years. Cannabis grows over a wide variety of geographic terrains, altitudes, and latitudes. It is grown in many countries and on all continents. Although it prefers the higher temperatures and longer growing seasons of the equatorial areas, it has been cultivated as far north as 60° latitude.

Cannabis and its related products comprise over three-quarters of the drugs material submitted to Forensic Science Laboratories in the UK for analysis. A number of forms of the drug may be encountered, including plant material, resin, and 'hash oil'. The active ingredient in all of these formulations is  $\Delta^9$ -tetrahydrocannabinol (THC). Also found is  $\Delta^9$ -tetrahydrocannabinolic acid which is converted to THC through smoking and the compounds  $\Delta^8$ -tetrahydrocannabinol (an isomer of the active ingredient), cannabidiol (the precursor), and cannabinol (the degradation product) (Figure 3).

**Fresh plant material** Cannabis plant material can occur as live plants, or as dried plant material. It is important when examining plant material that it should be in the dried state as water content will effect any weight measurements, a crucial factor in determining the seriousness of any charges. Male and female cannabis plants are separate with the male plant flowering before the female to ensure cross-pollination. The plant grows between 30 cm and 6 m in height and grows from seed to maturity in

**Figure 3** Main cannabinoids.

~3 months, though harvesting can occur after 2 months. The leaves are palmate with serrated edges and are opposite and alternate around a hollow four-cornered stem. The leaves are coated with upward pointing unicellular hairs called trichomes. Warty walled cystolithic trichomes are found on the stems and leaves together with a few glandular trichomes, which contain the THC. The greatest concentration of glandular trichomes is in the flowering tops of the plants and those of the female plant have a greater concentration of THC. Material prepared from the flowering tops or leaves usually contains 0.5–5% THC.

**Dried plant material** This may occur in various ways. Low quality products contain stalks, seeds, leaves, and flowering tops. This may be compressed into blocks (West African and Caribbean material) or as loose material or rolled up and wrapped in vegetable leaves (Central and Southern Africa). High quality material contains mostly flowering tops and can be found rolled up or wrapped around bamboo sticks ('Buddha' or 'Thai' sticks) or sieved ('Kif') and generally originates from Southeast Asia or parts of Africa.

**Resin (hashish)** This is also produced directly from the plant material. The glandular trichomes produce a resin, which is scraped from the surface of the plant and pressed into blocks. Hashish contains ~2–10% by weight of the active constituent,  $\Delta^9$ -THC. Most resin is produced either in the Indian subcontinent or parts of the Mediterranean. Usually between 100 and 400 mg of resin are used in a joint, though this varies from user to user. Mediterranean resin is made by threshing the herbal material, sieving to remove seeds

and stems, and the remainder compressed into slabs. The final material is light in color and quite brittle. Indian subcontinent resin is quite sticky and is removed from the plant by rubbing the plant and then molded into slabs. The final material is dark brown and sticky. When examining resin several facts are recorded, including whether or not the blocks seized fit together, any striation marks (cutting marks), which may be present and whether these can then be linked to a cutting instrument. The color and different layers within the resin block should also be examined and recorded.

**Hash oil** This is a manufactured product of cannabis and is produced by extracting the whole plant material using an organic solvent (usually alcohol or ether). On extraction the resulting oil can contain between 10 and 30% by weight of  $\Delta^9$ -THC. The oil is used in various ways including smoking with tobacco.

**Worldwide cannabis production and trafficking** It is estimated that 20 000–30 000 tons of cannabis are produced worldwide per annum. Cannabis trafficking has been increasing in response to a high and rising demand. Southern Africa (South Africa, Lesotho, Malawi, and Swaziland) is one of the largest producing regions exceeding that of Morocco, which used to be the world leader in production. Most of the cannabis grown in this part of the world is intended for local consumption, large shipments are being sent to Europe and North America. Mexico, the largest cannabis producing country in the Americas is the primary supplier of herbal cannabis to the USA, and Jamaica supplies large quantities of cannabis oil to Canada, either directly or through the USA.

**Cannabis trafficking in the European Union** Approximately 40 million Europeans use cannabis each year with an estimated 1 in 4 15–34-year olds having smoked cannabis either as herbal material or cannabis resin. Most resin is brought in through Spain from Morocco with lesser amounts transported from Pakistan, Afghanistan, and Central Asia via Eastern Europe. Herbal cannabis originates mainly from Columbia, Jamaica, and Africa (South Africa, Nigeria, and Ghana) and is transported by sea into Spain and Portugal for distribution throughout Europe. The Central Asian Republics, where vast fields of cannabis cover several hundreds of thousands of hectares, remain for the time being a major source of supply for the illicit Russian market. Much herbal cannabis is also home grown in Europe particularly using hydroponic techniques, especially in the Netherlands.

## Tryptamines and Lysergic Acid Diethylamide

Tryptamines are naturally occurring alkaloids found in a variety of plants and life forms around the world and exist in more than 1500 natural varieties. The basic element of tryptamine is the indol structure and tryptamine itself is an endogenous amine found in the human brain. Serotonin and melatonin are two essential tryptamines present as neurotransmitters in the brain. Tryptamines can be also produced either completely synthetically or semisynthetically (Figure 4).

Dimethyltryptamine (DMT), which is an active principle of various South American snuff, such as 'COHOBA' and 'YOPO'. It has been produced synthetically for a number of years, but its abuse has been restricted to a small number of dedicated users. Bufotin is very similar to DMT from a chemical point of view. It can be found either in the skin secretions of toads or in combinations with DMT in different trees in South America (for example, YOPO tree).

Psilocybin and psilocin are found in at least 15 species of mushrooms – so called 'magic mushrooms' – belonging to the genera *Psilocybe*, *Panaeolus*, and *Conocybe*. If a seizure contains whole or parts of mushrooms, the examination should include a description of the shape, size, and color of the fungus, as well as information regarding the gills, spores, cap, and stalk. Identification of fungi is difficult and should be performed by experts in that field. Illicit trafficking of cacti, which contain the psychoactive agent, mescaline, is also known. This drug occurs in at least three species of cacti. The most common illicit form of mescaline is produced as dried disk shaped cuttings taken from the tops of the cacti and called 'mescal buttons'.

Lysergic acid diethylamide (LSD) is a semisynthetic drug, which was first synthesized by Albert Hofmann in 1938. The starting materials are the lysergic acid compounds of the ergot, which is a spore capsule of a parasite mushroom. On the illicit drug market LSD has been sold in the form of impregnated paper (blotters/trips), microdots,

**Figure 4** Tryptamine and LSD.

thin squares of gelatine (window panes), or impregnated on sugar cubes. Stamps or blotters are the common dose form. They are made by impregnating paper with a solution of LSD in alcohol. These papers are 'trade marked' with various designs.

Analysis of such drug seizures should be carefully carried out and extreme caution should be taken as this drug readily penetrates the skin. Protective clothing should be worn at all times. If the presented drug sample is composed of sheets of absorbent paper the size and number of dose units, depth of perforations, and color and style of design should all be measured and recorded. If the drug is contained in powder or microdot form then it should be examined microscopically to identify any adulterants which may be present and can be subjected to further analysis. These usually include, dextrose, lactose, starch, talc potato starch, or maize. Dosage units can vary between 20 and 500 µg of LSD depending on the substrate used.

## Synthetic Drugs

### Amphetamine and Amphetamine-Type Stimulants

From a chemical point of view all amphetamine-type stimulants (ATS) are related to  $\beta$ -phenethylamine, which is the basic element of the body neurotransmitters (such as dopamine and adrenaline) that convey the neuronal information of the central and vegetative nervous system. Amphetamine was first synthesized in 1887 but was not used for medical purposes until the early 1930s, when it was found that it increased blood pressure, stimulated the central nervous system, was effective against asthma, and was useful in treating an epileptic seizure disorder. On the illicit drug market amphetamines have been sold in the form of powders, liquids, crystals, tablets, and capsules.

The most common amphetamine derivatives in the illicit drug market include amphetamine sulfate, methylamphetamine, methylenedioxy amphetamine (MDA), methylenedioxy methyl amphetamine (MDMA), and methylenedioxy ethyl amphetamine (MDEA). Dosages in powders and tablets vary considerably but are generally in the range of 50–250 µg of drug in a single dose. Most, if not all, amphetamine and related compounds are synthesized in clandestine laboratories by various synthetic routes (Figure 5).

**Ecstasy** When the term Ecstasy was first used in the early 1970s, it was an American street name for preparations containing the active agent MDMA. Now the term describes tablets or capsules predom-

**Figure 5** Amphetamines.

inantly containing one or more (or combinations) of psychotropic active agents derived from the  $\beta$ -phenethylamine group. It is becoming more and more common to compress amphetamine/methamphetamine into tablets, which are then also marketed as Ecstasy.

### Trafficking

*Amphetamine and Ecstasy use and trafficking in the European Union* Synthetic drugs particularly amphetamine and Ecstasy are the second largest type of drug consumed in Europe. Unlike with other drugs of abuse the EU is the major producer of these compounds and has a huge export market to other parts of the world particularly the USA, Canada, Australia, Asia, and Africa. Illicit amphetamine and Ecstasy laboratories have been found in 10 member states of the EU, particularly Belgium, the Netherlands, and the UK. Many laboratories are also known to exist in Eastern European countries such as Poland, Bulgaria, the Czech republic, and the Baltic states. These laboratories can vary from simple kitchens to professional laboratories with consequent variability in production capacity. Such laboratories also produce large quantities of chemical waste with associated disposal problems.

### Barbiturates

Barbiturates are therapeutically used as sedatives, hypnotics, anesthetics, and anticonvulsants. Virtually all barbiturates on the illicit drug market come from licit sources. There are 12 barbiturates recognized and scheduled by the United Nations and occur mainly as capsules and tablets and in some cases as injectable solutions. Illicit compounds occur as mixtures of barbiturates, or mixed with other drugs such as caffeine, aspirin, codeine, or in some cases heroin (Figure 6).

**Figure 6** Barbiturate structure.

### Methaqualone and Meclaqualone

Methaqualone was first synthesized in 1951 and introduced as a new drug that produced sedation and sleep in 1956. Methaqualone has been initially designed to counter the nervous damages caused by long-term consumption and to reduce the risk of the dependency potential of barbiturates. Interest in methaqualone rose dramatically in recent years. Its popularity was due to its undeserved reputation as an 'aphrodisiac' often in combination with diphenhydramine. Because of its strong habit-forming properties the drug was placed in the list of controlled substances and the legal manufacturer stopped its production and removed it from the market in 1984.

Methaqualone and meclaqualone were prepared as nonbarbiturate sleeping tablets, though they have also legally been used as hypnotics in some European countries. They appear on the illicit drug market either through diversion from the legitimate pharmaceutical trade or through illicit synthesis. The illicit samples are usually brown or gray powders with varying degrees of purity. Methaqualone is also used sometimes as a cutting agent for heroin.

### Benzodiazepines

Benzodiazepines, therapeutically used as tranquilizers, hypnotics, anticonvulsants, and centrally acting muscle relaxants, rank among the most frequently prescribed drugs. In 1960, the first benzodiazepine, chlordiazepoxide, was introduced. To date, more than 50 benzodiazepines have been marketed in over 100 different preparations. They appear mainly as capsules and tablets, however, some are marketed in other forms such injectable solutions or powders. Benzodiazepines were introduced to replace barbiturates and methaqualone as tranquilizers, hypnotics, anticonvulsants, and muscle relaxants. Currently there are 33 benzodiazepines on the control list all of which appear as tablets or capsules, though some also appear as vials or powders for preparation of injection (Figure 7).

**Figure 7** Benzodiazepine structure.

On the illicit drug market, diazepam ('Valium'), temazepam (often referred to as 'jellies'), and flunitrazepam ('Rohypnol') are used as drug substitutes, as additives in drug-preparations, or in combination with alcohol, as methods of incapacitating individuals ('Rohypnol' is sometimes known as a 'date rape drug'). Virtually all of the benzodiazepines in the illicit market result from diversion from legitimate sources and there is no evidence of clandestine manufacture.

### Phencyclidine and Analogs

Phencyclidine (PCP) was synthesized and tested in the early 1950s and recommended for clinical trials as an anesthetic in humans in 1957. In 1965, further human clinical investigation of PCP was discontinued and the compound was marketed commercially as a veterinary anesthetic. PCP became available through the drug culture in the late 1960s, referred as 'PeaCePill', commonly sold as 'angel dust', 'crystal', or 'hog', on the illicit market in powder, tablet, leaf mixture, and 1 g 'rock' crystal forms, usually taken orally, by smoking, snorting, or intravenous injection. The laboratory synthesis of PCP and approximately 120 related substances such as Eticyclidin (PCE) or Tenocyclidin (TCP) is cheap but also work-intensive and time-consuming.

A structurally related anesthetic, ketamine ('Special K'), has been developed and has recently gained popularity as it is not controlled by legislation in most countries.

### Gamma-Hydroxybutyric Acid

Gamma-hydroxybutyric acid (GHB) is a drug that is very similar to a natural chemical in the human brain called gamma-aminobutyric acid (GABA). GHB is a simple sodium (or potassium) salt of 4-gamma-hydroxybutyric acid. The street names are 'liquid

E', 'liquid ecstasy', or 'fantasy'. The forms of use are tablets, white powder, or solutions (dissolved in water or other liquids). GHB (like Rohypnol) is sometimes added to alcoholic drinks as methods of incapacitating individuals and is also known as a 'date rape drug'.

Originally GHB was marketed as a supplement replacement for L-tryptophan, an amino acid. Since the early 1990s, it is being used illicitly by athletes and bodybuilders, believing that its growth hormone releasing effects contribute to anabolism and lipolysis, or misused as a sleep aid and for weight control. GHB can be very easily prepared from gamma-butyrolactone (GBL) – a common industrial chemical for paint removers – by alkaline hydrolysis. The clandestine manufacture of GHB requires no prior chemical expertise as evidenced by the simplistic

instructions given in the underground publications or on the Internet.

### Paint Evidence and Its Properties

When two objects come in contact according to a given intensity, material will be transferred, persist, and can be recovered. If an object is coated, it is susceptible to leave its own paint and/or to import on its surface the one coming from the other object as traces in the form of multilayered flakes, chips, smears, or powder. The composition, form, quantity, and location of these traces can provide important information about their origin, the criminal action occurred, or the course of events in connection with crimes against people (e.g., hit-and-run accidents), property (e.g., vehicles road accidents, breaking and entering, vandalism), capital crimes (e.g., terrorist attacks, murder, etc.), and other offences involving the use of painted objects.

Paints are extremely complex in their composition. Depending on their intended use and the prescribed method of application, the paint formulations are composed of a multitude of individual components. These can be assigned to four main groups according to their functions showed in **Figure 1**.

The term paint is known to indicate a suspension of pigments contained in a nonvolatile vehicle liquid

used as a binder; on the other hand, the term coating designates a liquid or a liquefiable material converted to an opaque solid film applied to a surface. Pigment-free paint formulations based on drying oils and resins in organic solvents are referred to as varnishes. Lacquers are thermoplastic solution paints or varnishes which physically dry through ordinary evaporation of solvents rather than by oxidation or polymerization.

The primary purpose of paint is to hide the surfaces of the substrates and to protect them from corrosion and degradation. Therefore, important

### Paint Evidence and Its Properties

When two objects come in contact according to a given intensity, material will be transferred, persist, and can be recovered. If an object is coated, it is susceptible to leave its own paint and/or to import on its surface the one coming from the other object as traces in the form of multilayered flakes, chips, smears, or powder. The composition, form, quantity, and location of these traces can provide important information about their origin, the criminal action occurred, or the course of events in connection with crimes against people (e.g., hit-and-run accidents), property (e.g., vehicles road accidents, breaking and entering, vandalism), capital crimes (e.g., terrorist attacks, murder, etc.), and other offences involving the use of painted objects.

Paints are extremely complex in their composition. Depending on their intended use and the prescribed method of application, the paint formulations are composed of a multitude of individual components. These can be assigned to four main groups according to their functions showed in **Figure 1**.

The term paint is known to indicate a suspension of pigments contained in a nonvolatile vehicle liquid

used as a binder; on the other hand, the term coating designates a liquid or a liquefiable material converted to an opaque solid film applied to a surface. Pigment-free paint formulations based on drying oils and resins in organic solvents are referred to as varnishes. Lacquers are thermoplastic solution paints or varnishes which physically dry through ordinary evaporation of solvents rather than by oxidation or polymerization.

The primary purpose of paint is to hide the surfaces of the substrates and to protect them from corrosion and degradation. Therefore, important

**Figure 1** Main constituents characterizing paint materials formulation.

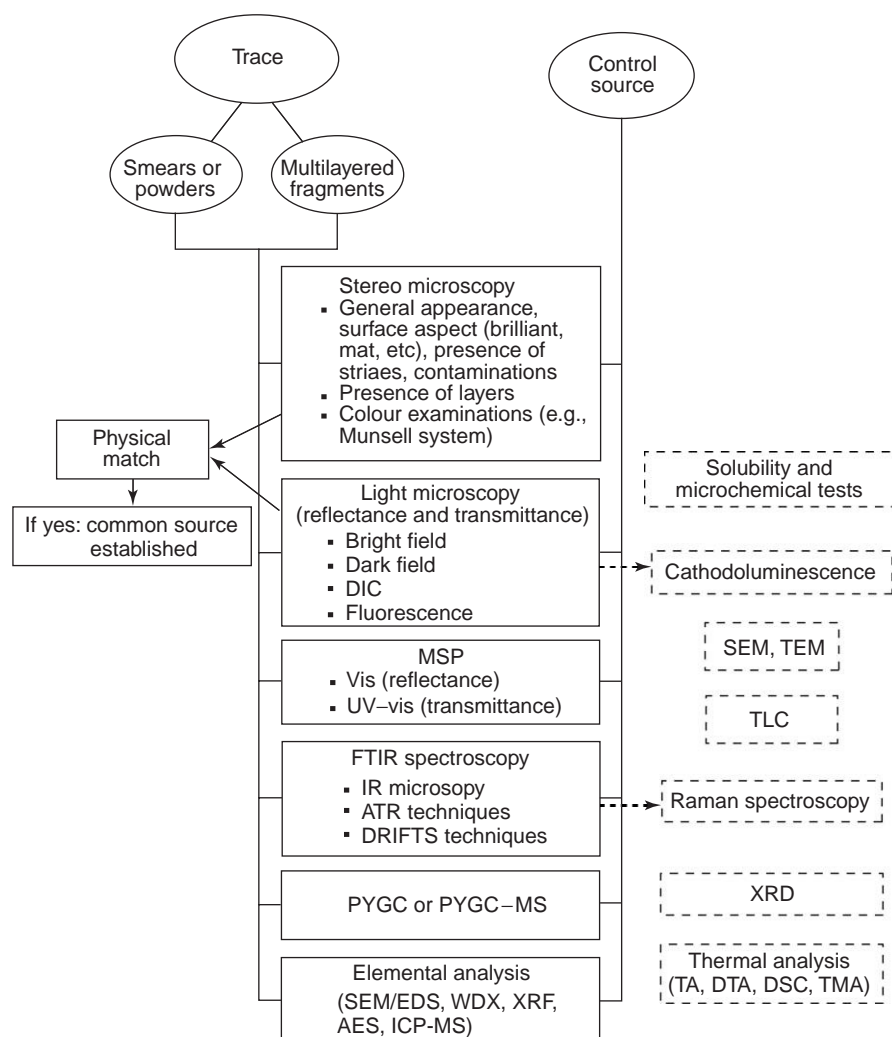

properties of such material are resistance to chemicals, abrasion, and weather conditions. The appearance of the surface with such features as gloss, color, or completely smooth or textured surfaces is almost as important. In order to guarantee lasting protection and decorative properties, the surfaces are often pre-treated in several stages and then layered in several additional stages with compatible paint materials (sealer, primer, primer-surfacer, topcoat). Thus, the final product in the sequence of operations is generally a multilayered coating system. During the period of service, additional layers of paint and surfacer may be applied on top of such systems during repairs (e.g., a painted vehicle body).

The main emphasis in forensic paint analysis lies in the comparison of materials: the physical and

chemical characteristics of a paint trace (suspect or unknown or questioned sample) and a control paint sample (or reference or known sample) are compared to establish if they have a common origin. A typical analytical sequence for paint is illustrated in Figure 2.

One of the main problems in comparative material analysis is how to interpret matching analytical data. Paints are mass products which are often produced in considerable annual tonnages: to come to the correct conclusions about the evidential value of the results, the forensic scientist must be able to distinguish between paints from batch to batch, to know information on the influence on analytical results of material ageing, and to find dealing with errors in application and defects in materials. Statistical data on the

**Figure 2** Comparative analytical sequence for paint evidence with its control paint known source. Such sequence depends on the quality and quantity of paint evidential material recovered, on the equipment of the laboratory and on the personal choice of the forensic scientist. At every stage of the sequence, if the questioned and the known samples result undifferentiated, one continues with the following examinations. If the trace and its control are differentiated with a given technique and if the differentiation cannot be explained, a common origin can be excluded.

frequency of occurrence expressing the rarity of certain combinations of paint components in a given relevant population are also included. The availability of a broad spectrum of microscopic techniques combined with methods of instrumental microanalysis is indispensable for forensic investigations with the objective of classification, identification, discrimination, or evaluation of a common source or moreover of a contact that occurred between painted surfaces.

A further important function is the determination of the origin of unknown coating systems (e.g., the make, model, and year of a vehicle from a fragment of paint recovered from the scene of a hit-and-run accident) in the aim to supply useful investigative information to the police. Other than classical vehicle ones, product coatings (e.g., tools or spray paints) or architectural (or household) paints can be typically submitted to a forensic laboratory for analysis. Such investigations are also necessary in the field of artistic paints in connection with art forgeries (e.g., certification of authenticity), for the determination of the age of coatings (e.g., anachronisms), or to supply useful information for the conservation or restoration of such paints.

## Sample Collection and Pretreatment Prior to Analysis

The detection and collection of paint traces (unknown or questioned samples) is fundamental because every mistake or forgetfulness at this stage will be irreparable. The form, the quantity and the quality of paint material collected will affect the number and the capacity of the available analytical methods.

For paint traces recovered on a solid surface as a vehicle, a doorway, a window frame, or a wall, paint fragments are isolated with tweezers; smears or powders are recuperated by scratching by means of a knife or a razor blade (recuperating the paint in a sheet of paper). Tape lifts should only be used if other methods fail.

Where the object is transportable (e.g., tools), it is suitable to bring it to the laboratory (covering the paint trace with papers) for a research under a stereo microscope and the following collection will be undertaken by means of tweezers or a metal point; if circumstances allow it, it would be useful to cut vehicle body or to collect a piece of the support as a wooden forced doorway or a tagged wall. If possible, in searching for paint traces, the scientist must consider the possibility of a cross-transfer. Paint fragments on textiles are searched with lens and under the stereo microscope using tweezers, and then

shaking recuperating fragments on a cleaned surface; finally a vacuum cleaner can be used.

Control paints (known samples) collection must be undertaken close (but not within) to the zone of contact where the foreign paint traces are sticking; this is important because of the changes of the paint system within big surfaces as those of vehicles.

Concerning the paint analysis, reproducible and correct measurements can only be achieved if the sample material is optimally prepared. In the preparation of paint traces it is essential that characteristic features such as common broken edges, striation marks, or texture effects on the upper or lower surfaces are not destroyed.

For multilayered paint fragments, in order to determine precisely the morphological features (number and thickness of layers, their color, luminescence, etc.), it is necessary to prepare cross-sections: the fragments are embedded in a suitable resin and either ground and polished in one step with the aid of an ultramilling cutter or processed in a grinding and polishing device. A resin based on mono- and difunctional methacrylates Technovit 2000 LC (Heraeus Kulzer, GmbH; hardening process 20 min by using blue light) and the epoxy resin Devcon 5 (hardening time: 15 min) are proven cold embedding materials. These materials dry quickly and do not react with paints. Microtome sections should be obtained for optical and scanning electron microscopic (SEM) examinations, for microspectrophotometry (MSP) and infrared (IR) spectroscopy.

## Optical Examination and Light Microscopy

Stereo microscope (magnification of 5–40 $\times$ ) is first used to observe the general appearance of the sample (shape, color, presence of layers, etc.) in order to establish if it can be a paint material. Color (intended as hue) is the first feature observed, being the most eye-catching one: this stage is subjective but it is useful for a first description and evaluation of that feature. There exist systems based on the classification in a 3D color space supplying labels or coordinates: some examples are the most used Munsell color coordinate system, the Standard color chart DIN 6164, or the Natural color system and the Muthen Handbook of Colours. Concerning automotive paints, Color collections distributed by the main paint producers (Du Pont, ICI, Nippon Paint, Glasurit BASF) have proved successful, including touch-up paints of standard car colors and nuances caused by weathering. The most useful today are the Akzo Colorscala (Akzo Coatings by, The

Netherlands) the Euro Colour Catalogue (Dupont Colour Book), and the Glasurit (Color-Profi-System, BASF, Germany). If the unknown and the control samples permit it, a physical match, even if very rare, must be searched by observing the edges and irregular contours of fragments and their surfaces striae (e.g., scratches).

Then, microscopic examinations follow: optical research microscopes allow to determine the number, thickness, and color sequence of layers in paint fragments, and to recognize the textures as well as fundamental features of pigment and extender mixtures. Bright field and dark field illuminations, polarized light microscopy (incident and transmitted), particularly the differential interference contrast (DIC) procedure, and fluorescence microscopy are necessary for paint examinations (see **Figure 3(A)–3(E)**).

Paint fragments are first placed on a microscope slide without previous preparation to determine whether there are significant imperfections (e.g., striations marks, 'fish eye' depressions, etc.) and other textures on the surfaces: DIC procedure is the most suitable. The determination of particle form, size class distribution, and the number of effect pigments (metal and pearl luster pigments) can also be accomplished quickly with plane-polarized light in incident light/bright field without prior sample preparation. All analyses for the determination of paint structures and for the most complete description of the morphological and physicochemical features of the colored pigments and extenders used in paints (color, size, crystal habit, crystallinity, and refractive index) must be carried out at the highest magnification possible (250–1000 $\times$ ) in transmitted light with bright field, dark field, and double polarization techniques on 3  $\mu\text{m}$  microtome sections preparations (embedded parallel or perpendicular to the surface). Fluorescence microscopy at an excitation wavelength of 365 nm must also be used for the characterization of pigments, additives, and film-forming components.

## Microspectrophotometry

The spectrophotometric technique is very useful for comparative purposes for a color classification system in a database and for the identification of individual organic or pearlescent (or interference) pigments or additives such as ultraviolet (UV)-absorbers; batch-to-batch discrimination is also possible for analyzing the basecoats. MSP permits to measure absorption spectra in a given spectral range comprising typically 250–780 nm and to calculate

the tristimulus CIE color coordinates. For paint analysis two main techniques are used: visible reflectance for the objective color measurement and UV–visible transmittance particularly for the discrimination of samples of similar shades of color and for the detection of additives.

Color is one of the most important as well as the most eye-catching characteristics of microscopically opaque objects such as paint. Color measurements are carried out using a single-beam technique (previously measuring a standard on a perfectly white reflective object as a pure barium sulfate tablet or a polished opal glass) with microspectrophotometers fitted with image-side monochromators with geometry 45°/0° (like J&M Tidas diode array spectrometers and the Zeiss MPM 800-system).

Visible reflectance spectra can be obtained from upper surfaces or from individual layers in a cross-section. Areas ranging from 6  $\times$  150 to 20  $\times$  80  $\mu\text{m}^2$ , respectively are measured. For microscopic color measurements only the measuring parameters of 45°/0° are realizable.

Since many paint layers already exhibit inhomogeneities in such dimensions for the calculation of color data (tristimulus values and chromaticity coordinates), it is necessary to use mean reflectance values derived from three to five individual measurements of different sample areas. For individual measurements, the sample surfaces, especially in the case of paints containing plate-like pigments (light interference and/or color variable pigments), should have varying orientations to the adjustable measuring aperture.

UV–visible spectra are accessible by means of analysis of thin sections of paint with microspectrophotometers equipped with quartz optics; quantifiable results are obtained from 3- $\mu\text{m}$ -thin sections fixed on quartz specimen slides. The reproducibility of absorbance spectra is very high for solid as well as for metallic paints even when a small measuring aperture (10  $\times$  30  $\mu\text{m}$ ) is used. Batch-to-batch discrimination is therefore possible. Individual organic pigments are also identifiable using UV–visible spectra when, for example, they are present in the form of aggregates and reagglomerates in the base coats of two-coat metallic paints.

UV-absorbers (e.g., hydroxyphenylbenzotriazole) can also be identified in 20- $\mu\text{m}$ -thin sections of the clear coats of two-coat metallic paints (**Figure 4**).

Discrimination between different vehicles which were originally painted in an identical manner is based on the varying decrease of the UV-absorber concentration with time, depending on the substance class of light stabilizer (e.g., oxalanilides, benzophenones) and the type of environmental conditions.

**Figure 3** A multilayered paint sample taken from a vehicle with two-coat metallic top coat: burgundy red (BMW 199). (A) Surface as viewed under polarized/reflected light (500 $\times$ ; scale bar: 30  $\mu$ m). (B) Section (3  $\mu$ m) sliced parallel to the surface of the metallic base coat; transmitted light (500 $\times$ ; scale bar: 30  $\mu$ m). (C) Cross-section (3  $\mu$ m) with the layer sequence (from the bottom): primer, surfacer, base coat, clear coat; transmitted light (500 $\times$ ; scale bar: 30  $\mu$ m). (D) Sample as (C): fluorescence with 365 nm excitation wavelength (500 $\times$ ; scale bar: 30  $\mu$ m). Cross-section of a fragment of a seven-layered household paint containing different amounts of  $\text{CaCO}_3$  phases (scale bar: 100  $\mu$ m). (Lower) Transmittance spectra of the clear coats; transmission measurements made on a 20- $\mu\text{m}$ -thick section.

## Vibrational Spectroscopy

### Infrared Spectroscopy

IR spectroscopy is particularly used for the identification of the main components like binder types (see Table 1), pigments and extenders (see Table 2), as well as for their classification.

Discriminations within a binder type are possible by means of identification of modifiers, for example. Further discriminations are based on the comparison of the relative intensity of absorption bands. The capacity for monitoring the chemical changes which occur from UV degradation (weathering) can also be used for the differentiation of paints.

Thanks to its time and signal-to-noise advantages as well as greater wavelength accuracy, Fourier transform IR (FTIR) spectroscopy has become a technique of choice for the analysis of transmissive or reflective forensic paint materials, especially if coupled to a microscope. By using FTIR microscopy good spectra can be obtained from paint layers as

**Table 1** IR characteristic absorptions peaks or bands of some common binder types; characteristic bands in bold (consider an incertitude of  $\pm 10 \text{ cm}^{-1}$ )

Binder	IR absorption peaks or bands ( $\text{cm}^{-1}$ )

small as  $10 \times 20 \mu\text{m}^2$ ; for this purpose microtome sections of 3–5  $\mu\text{m}$  are particularly suitable.

Diamond anvil cells (low-pressure or high-pressure) have long been used in the successful measurement of transmission spectra of small paint samples: these latter are squeezed with light pressure between two type II diamonds into a transparent film to obtain an appropriate thickness. For transmittance analysis, potassium bromide, KBr (or cesium iodide, CsI) micropellet constitutes a simple solution.

Different sampling techniques are available for the handling of micropaint samples. Among these techniques are diffuse reflectance IR Fourier transform spectroscopy (DRIFTS) and attenuated total reflection (ATR), using accessories like 'SplitPea' or 'Golden Gate' or a microATR objective for IR

microscopes. Using DRIFTS, single-layer metallic paint fragments can be analyzed directly without sample preparation; the use of abrasive disks (3 mm diameter) coated with silicon carbide (SiC) is an alternative sampling technique for DRIFTS. With this technique the sample is simply rubbed on the SiC paper and then measured *in situ* on the surface of the paper.

ATR accessory can also be employed for reflectance analysis, particularly for the surfaces of smears sticking on a given support: with, e.g., 'SplitPea' accessory (Harrick Scientific Corporation) very small paint traces can be measured ( $<0.3$  mm) without sample preparation, on the basis of internal reflection, external reflection, or in-line diffuse reflection spectroscopy.

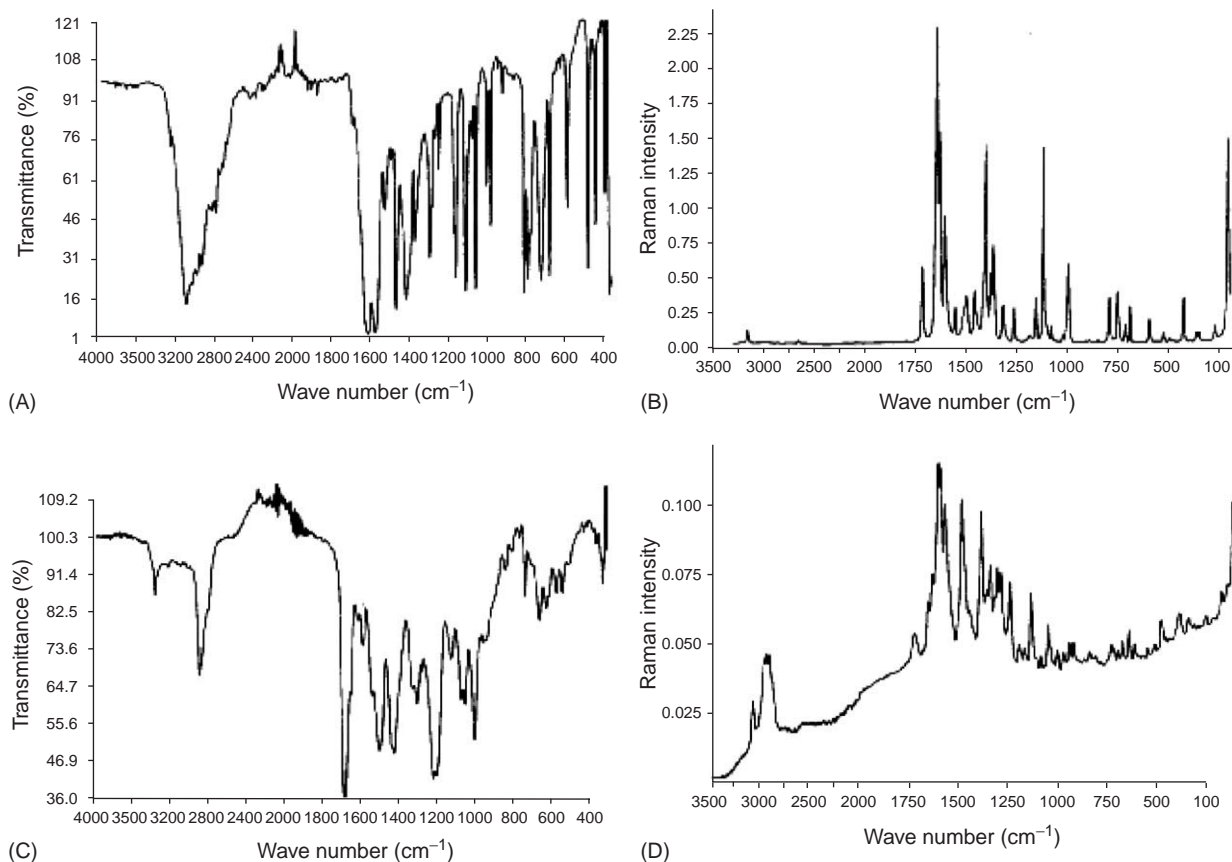

For paint analysis, a spectral range comprising between 4000 and 600  $\text{cm}^{-1}$  is usually used, but for the identification of some inorganic pigments and extenders (e.g., titanium dioxide), a lower frequency

domain is necessary: using deuterated triglycine sulfate (DTGS) as detector and CsI for the interferometer system instead of mercury cadmium telluride (MCT) and potassium bromide (KBr), spectral data until 200  $\text{cm}^{-1}$  can be obtained.

IR spectra also constitute the starting point for the research of vehicles involved in hit-and-run accidents: databases are built containing IR information of every layer characterizing manufactured vehicles. Some important examples are the European Collection of Automotive Paints (EUCAP) Database and the FBI/RCMP Paint Data Query (PDQ) Automotive Paint Database.

### Raman Spectroscopy

Raman spectroscopy is complementary to IR spectroscopy (Figure 5): for paint, while IR spectroscopy is used to mainly characterize binder type and some inorganic pigments, Raman techniques are more

**Figure 5** FTIR spectra and Raman spectra obtained from the pure C.I. Pigment Red 254 and from microtraces (3  $\mu\text{g}$ ) of an alkyd-melamine paint containing 4% of the C.I. Pigment Red 254. This example clearly reveals the complementary information obtainable from using both IR and Raman spectroscopy for paint analysis. In the IR spectrum of the paint sample nearly all the absorption bands of the pigment are masked by those of the resin; however, the fingerprint of the pigment can be seen in the Raman spectrum. (A) Diamond anvil cell spectrum of C.I. Pigment Red 254 (1,4-diketo-3,6-diaryl-pyrrolo(3,4-c)pyrrole); (B) NIR-FT Raman spectrum of C.I. Pigment Red 254; (C) Diamond anvil cell spectrum of the vehicle paint Tornado red (Volkswagen) containing 4% C.I. Pigment Red 254; and (D) NIR-FT Raman spectrum of the vehicle paint Tornado red (Volkswagen).

suitable for the identification of the main organic or inorganic pigments present. Extenders can be detected with both techniques.

Depending on instrumentation, different laser wavelengths are available: near IR lasers (e.g., Nd-YAG, diode array) are useful principally for red, orange, yellow, brown, and violet pigments. Visible lasers (e.g., argon, helium, and neon) are useful for the detection of blue and green pigments (e.g., phthalocyanines).

Fluorescence constitutes the greatest disadvantage of the Raman technique hiding spectral information. In the 1990s, Fourier transform Raman spectroscopy was developed on the basis of a near IR laser source being less energetic to produce fluorescence. However, with the introduction of the Peltier-cooled charge couple device (CCD) detector being more sensible and polyvalent for several laser sources, dispersive Raman spectrometers were reevaluated. The possibility to benefit from several laser sources going from the UV, visible, and to the near IR mounted on the same spectrometer constitutes an interesting tool for paint analysis. Moreover, research microscopes coupled to spectrometers permit to focus a microdetail of the sample (spatial resolution until  $\sim 1\ \mu\text{m}$ ).

Raman spectroscopy is above all applied in the field of artistic paints detecting inorganic pigments (e.g., vermilion, ochres) but some applications were also carried out for automotive paints allowing principally the detection of organic (e.g., diketo pyrrolo pyrrol, quinacridones) and inorganic (e.g., molybdate orange, chrome yellow) industrial pigments and some extenders (e.g., anatase) (see **Table 3**).

## Pyrolysis Gas Chromatography and Mass Spectrometry

Pyrolysis gas chromatography (PyGC), particularly when combined with MS, PyGC and mass spectrometry (PyGC-MS), is a powerful, fast, and elegant analytical method for the characterization of polymers. In addition to qualitative and quantitative detection of monomer units and the identification of comonomers, it also provides additional information about additives and impurities. In addition, the chromatogram, especially the reconstructed total ion chromatogram of the pyrolysis products, the pyrogram, can serve as a 'fingerprint' of the paint samples. The most frequently used pyrolyzers are the Curie-point type, the furnace type, and the pulsed filament type. In terms of reproducibility, an indirect heating system using a platinum coil (CDS system) has proved very successful. Among the columns, fused capillarity columns with nonpolar stationary phases or with intermediate polarity are generally accepted. As a rule, flame ionization detectors (FID) or mass spectrometers (MSs) (quadrupoles and ion traps) with dedicated data systems are used as detectors or identification systems.

Information about the composition of the sample material can be significantly increased if the paints have been derivatized during pyrolysis. Tetramethylammonium hydroxide (TMAH) is used as a derivatizing reagent for structure elucidation of alkyd, unsaturated polyester, epoxy, and phenol-formaldehyde resins. The derivatization of paints, whose pyrolysis products elute at very low retention times (such as formulations based on polyvinylacetate

**Table 3** Raman scattering bands of some common pigments and extenders

copolymer or on cellulose acetate butyrate), is accomplished with tetrabutylammonium hydroxide (TBAH).

The detection and identification of polar components is also possible using simultaneous hydrolysis and alkylation. These are normally difficult or impossible to determine because they tend to remain on the column, cause peak tailing, show poor reproducibility, or lose their identity due to the formation of low molecular weight fragments. Thus, for example, methyl esters of polybasic acids and long-chain fatty acids and methyl ethers of polyhydric alcohols are formed from alkyd resins with TMAH, whereas in conventional PyGC, aldehydes are formed from polyols, and alkanes and alkenes from fatty acids (Figure 6).

However, some problems have been encountered using TMAH on-line methylation in a Curie-point pyrolysis unit: the reaction between TMAH and fatty (di)acids (azelaic, palmitic, and stearic) showed that different quantities of subproducts are formed varying the quantity of TMAH reagent: deepening of such method is suitable to understand the formation of such subproducts and the way to avoid it.

In addition to the identification of the main components, the presence of modifiers such as wood resin and epoxy resins in alkyds can also be proved. It is also possible to draw conclusions about the oil length and the degree of cure or the age of the alkyd resins.

By means of high temperature reaction with TBAH the identity of comonomers in polyacrylates can also be determined. Among the identifiable components are in particular hydroxy-functional and carboxy-functional monomers (e.g., hydroxyethylacrylate, acrylic acid, and methacrylic acid) as well as additives (e.g., cellulose acetate butyrate). These partially strongly polar compounds are either not identifiable at all with conventional PyGC or their presence leads to strong tailing. Since butyl esters are formed from the acids in the reaction with TBAH, which may already be present in the product as comonomers, the analysis results are not always unambiguous. To determine the compositions of acrylates, it is therefore advisable to compare pyrograms which have been obtained with and without the use of a derivatizing reagent.

With the introduction of the simultaneous pyrolysis and alkylation techniques, the capacities for identification, classification, and differentiation have improved significantly.

## Elemental Analysis Techniques

### Scanning Electron Microscopy and Energy Dispersive X-Ray Spectrometry

Scanning electron microscopy and energy dispersive X-ray spectrometry (SEM/EDS or SEM/EDX) is the

**Figure 6** Conventional pyrolysis (A) and simultaneous pyrolysis-methylation (B) of an orthophthalic alkyl melamine resin; capillary GC-MS-pyrograms (RIC). 1 = methacrolein; 2 = phthalic anhydride; 3 = phthalimide; 4 = pentaerythritol tetramethyl ether; 5 = octanoic acid methyl ester; 6 = hexanedioic acid dimethyl ester; 7 = decanoic acid methyl ester; 8 = dodecanoic acid methyl ester; 9 = orthophthalic acid dimethyl ester; 10 = azelaic acid dimethyl ester; 11 = tetradecanoic acid methylester; 12 = hexadecanoic acid methyl ester; 13 = octadecanoic acid methyl ester. (Instrument conditions: Pyrolyzer: Pyrola (Pyrolab, Lund/Sweden); pyrolysis temperature: 750°C; GC: Finnigan MAT 9610 fitted with a fused-silica column (DB 5; 0.25  $\mu$ m phase thickness; 0.25 mm internal diameter; 30 m in length); injection mode: splitless (20 s)/split 1:20; temperature program settings: 40°C, hold 2 min; increase at 10°C min<sup>-1</sup> to 280°C.) Mass spectrometer: Finnigan MAT 4500.

method of choice for the characterization of the morphology and the elemental composition of paint samples. A wide range of elements present on the periodic chart (in quantities  $\sim 0.1$  wt.%) can be detected for the identification of inorganic components as pigments and extenders (see Table 4).

**Table 4** Elements indicating the presence of some inorganic and organic pigments and extenders

<i>Pigments or extenders</i>	<i>Element(s)</i>
Yellow lead chromate	Pb, Cr, S
Chromium oxide	Cr
Iron ferrocyanide (Prussian Blue)	Fe
Ochres	Fe, Si
Aluminum silicate	
Kaolinite	Al, Si
Mica	K, Si, Al
Magnesium silicate (talc)	Mg, Si
Barium sulfate	Ba, S
Calcium carbonate	Ca
Monoarylide yellow (Azo)	Cl
Phthalocyanine Green	Cu, Cl, or Br

Organic pigments cannot be identified, but their presence is often indicated by the presence of some elements as chlorine and bromine or nickel, manganese, and copper (e.g., for phthalocyanines). In lake pigments this can also be seen in combination with barium or calcium and sulfur.

Scanning electron microscope (SEM) systems are ideal for a pictorial representation of morphological features of single layers of multilayered paint samples (particularly those not well contrasted by optical microscopy as the white ones) obtained by the contrast of secondary (SE) and backscattered electrons (BSE). An important advantage of SEM is the ability to analyze even the smallest smears: for this purpose the smears are lifted from the underlying material using double-sided adhesive tape transferred to the sample holder (e.g., slide). Twenty micrometers microtome sections of paint cross-sections are recommended. In order to avoid electrical charging the samples have to be carbon coated or transferred into the chamber of a low vacuum system.

The main emphasis of paint analysis with SEM concerns EDS or EDX. To compensate for inhomogeneities, the scanned sample areas should be as large as possible. At least two to three areas must be analyzed under standardized measurement conditions. Mapping procedures are recommended for the analysis of cross-sections. In this manner the thinnest layers on the upper and lower surfaces (e.g., zinc phosphate layers on the lower surface of vehicle paint fragments) can be described and analyzed. Metallic paints should be examined at higher magnification (10 000  $\times$ ) in aluminum-free areas.

For quantitative X-ray analysis, electron probe microanalyzers (EPMA, EPA, or EMMA) are able to determine the elemental concentration by X-ray emission from the microvolume of paint samples where a static electron beam interacts. However, due to inhomogeneity of paint samples nonquantitative

analysis based on the comparison of spectra or peak rationing is preferred.

### Wavelength Dispersive X-Ray Fluorescence

Wavelength dispersive X-ray fluorescence (WDX) detects X-rays according to their wavelength rather than their energy (see **Figure 3(G)** and **3(H)**). Because of the limited resolution capacity of lithium-drifted silicon detectors (Si(Li)-diodes), the peak areas from a series of elements as PbM-SK-MoL, TiK-BaL, or CaK-SbL lines, being important for pigment analysis, cannot be separated using EDS. In these cases correct analyses can only be achieved with a wavelength dispersive spectrometer.

### X-Ray Fluorescence Spectrometry

For X-ray fluorescence spectrometry (XRF) technique an X-ray excitation source is used and, compared to SEM/EDS, it is more sensitive to higher atomic weight elements and less sensitive to the lower atomic weight elements commonly found in extenders.

Successful X-ray fluorescence spectrometric attachments are those which allow observation of the sample during analysis (microscope or image sensor) and which have an adjustable sample stage. Such devices are generally equipped with capillary optics, a low power X-ray tube (150–350 W) and a Si(Li)-detector.

### Laser-Excited Atomic Emission Spectroscopy

Atomic emission from the laser-excited plume is monitored by an emission spectrograph; with Q-switch lasers even individual layers in cross-sections of paint fragments can be analyzed. Material consumption lies in the nanogram range. The sample is fixed on the edge of a glass microscope slide with the aid of double-sided adhesive tape. An advantage of this multielement system is the very high sensitivity; a disadvantage is the time-consuming evaluation of the results via a photographic plate or film.

### Inductively Coupled Plasma Techniques

Inductively coupled plasmas either combined with atomic emission spectrometers (ICP-AES) or mass spectrometers (ICP-MS) where samples are excited using a high-temperature gaseous plasma can be used for elemental analysis. Since the development of ICPs, most applications have required digestion of solid samples with heat and/or strong acids. The coupling of laser-ablation (LA) with ICP-MS has resulted in the development of extremely sensitive microprobes capable of determining most elements of the periodic table. Another advantage of the

technique is that LA-ICP-MS is point specific, that is, only the area ablated is subject to analysis. As a result, LA-ICP-MS has become one of the most exciting new fields of research in materials science in general.

## Solubility and Microchemical Tests

In some laboratories, comparative analyses begin with solubility tests. The difference between the suspect and the control samples can often be determined quickly through the reaction and the different solubility of the paint binders with a variety of chemical reagents (e.g., chloroform, acetone, concentrated sulfuric acid, etc.): only when differences cannot be detected with these tests is it necessary to employ instrumental methods.

Microchemical testing is not only based on dissolution of binders but also on pigment and binder color reactions with oxidizing, dehydrating, or reducing agents. These tests are destructive: diphenylamine (in concentrated sulfuric acid and glacial acetic acid) and LeRosen (formaldehyde in concentrated sulfuric acid) tests are typically used.

For both solubility and microchemical tests, reactions and color changes must be observed under a stereo microscope concurrently for unknown and control samples at different time intervals, in order to detect differences.

## Other Techniques

### Cathodoluminescence

Cathodoluminescence (CL) permits to give prominence to the layer sequence particularly white and off-white (e.g., pale yellow, cream colors) multilayered paint samples (see **Figure 3(F)**). It is the excitation of visible light or of radiation of adjacent wavelengths in semiconductors and insulators (e.g., inorganic pigments and extenders) when these are bombarded by electrons emitted from a cathode and accelerated in an electric field.

CL is well observable using optical microscopy as well as SEM. Worthwhile results can be obtained when a CL detector (photomultiplier) is coupled with a monochromator. The recording of CL-spectra allows differentiation of inorganic pigments and extenders which otherwise vary only in the type or number of lattice defects (e.g., vacancies, trace activators on interstitial lattice sites, etc.).

### Thin-Layer Chromatography

If solubility tests reveal that microtraces of paint contain organic pigments, these latter can be

identified by thin-layer chromatography (TLC) or by high-performance thin-layer chromatography (HPTLC). Silica gel is used as the solid phase and chloroform as the eluent in a mixture with aliphatic or aromatic hydrocarbons. These methods, however, can only be applied to a few classes of pigments being soluble. For light-fast polycyclic pigments (phthalocyanines, quinacridones, perylenes, perinones, dioxazines, indanthrones, isoindolinones, benzimidazolones) trifluoroacetic acid/water is used as extractor and eluent. Pigments are converted into mobilizable onium compounds and are separated onto C<sub>18</sub>-reversed phase plates. The identification is achieved by means of the  $R_F$  values but microspectrophotometric, IR, and Raman spectroscopic examinations can be added for this purpose.

### X-Ray Diffraction Spectroscopy

X-ray diffraction spectroscopy (XRD) techniques have been used for the analysis of inorganic pigments and extenders by analyzing the crystalline structure of the material rather than its elemental content: e.g., it is typically able to differentiate the crystalline forms of titanium dioxide, rutile, and anatase. The method is less suitable for the identification of organic pigments as they do not generally scatter X-rays well and they are often present in paints only in comparatively small concentrations. Additional difficulties occur in the interpretation of the results because the diffraction pattern sometimes exhibits only the most subtle differences within a class of organic pigments.

### Transmission Electron Microscopy

Methods of transmission electron microscopy (TEM) can also be applied to the pigments and extenders analysis. Morphological studies of shadowgraphs have proven reliable. During preparation, the paint microtraces (>100 µg) are dispersed in an ultrasonic bath after ashing (450–550°C) and sedimented onto appropriate sample holders (copper grid with pioloformfilm). The morphological structures of such powder preparations observed at 12 000–65 000 × magnification display a broad range of variation. They can be used together with EDS and electron diffraction for the identification of the material. Especially interesting results are obtained from the examination of paints with effect pigments (e.g., pearl luster pigments) (**Figure 7**).

In one analytical step it is possible to classify and identify the various pigments and extenders used and to describe the morphological features and anomalies which are phase-typical or which are the result of manufacturing. Proof that paints contain

**Figure 7** Transmission electron microscopy image of a pearl luster pigment; during preparation the microcrystalline nanometer thick layers of rutile have become separated from the undersurface and partially from the upper surface of the mica surface, so that the layered structure of the effect pigment is clearly visible (scale bar: 1  $\mu\text{m}$ ).

microtitanium dioxide (grain size 0.01–0.05  $\mu\text{m}$ ) or amorphous silicon dioxide, can be obtained by using TEM-examination.

### Thermal Analysis

Of the many methods of thermal analysis (TA), only a few have been used in forensic paint analysis: among them are differential thermal analysis (DTA), differential scanning calorimetry (DSC), and thermomechanical analysis (TMA). For example, DSC can provide information of the rate of ageing of oil-based paint media. The determination of the age of oxidative drying paint films is also possible with TMA. In this procedure the glass transition temperature ( $T_g$ ) is determined. With  $T_g$  determination it is also possible to describe the conditions under which the paint films were hardened (e.g., the stoving temperatures of vehicle paints). However, samples in sufficient amounts must be available in order to obtain reproducible results (sample size: disks with radius >2.5 mm and thickness of the order of 0.05 mm). Such large samples are seldom available. Therefore, for the purposes of forensic science TMA is not a suitable technique for the routine examinations of small paint fragments.

An interesting procedure in forensic paint analysis, however, is thermogravimetry–mass spectrometry (TG–MS), determining simultaneously TG curve and its first derivative, total ion current versus the TG temperature, single ion currents for selected molecular fragments versus TG temperature, and determination of the pigment/volume concentration of

inorganic components residue analysis for trace elements.

## Questioned Documents

**C Neumann and W D Mazzella**, University of Lausanne, Lausanne, Switzerland

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

A document – from the Latin *Documentum*, ‘which serves to educate’ – is conveniently defined as something that holds information. Although there are multiple ways to share information in our modern society, such as magnetic tapes, electric appliances (telephone), and electronic devices (computers), questioned document experts have traditionally focused on the examination of documents normally made of paper, which bear written or printed messages.

### Documents as a Support for Traces

In the forensic science field, the examination of questioned documents is one of the most commonly carried out tasks. Its primary aims are to provide information about the material (to describe the different materials used and identify their origin) and the history of a document (the presence of traces of erased or modified entries in order to arrive at the truth regarding their integrity).

Therefore, the techniques described in this article can be used to compare trace materials (papers, inks, or toners of the questioned document) with reference materials from known sources. This process is typically carried out during checking of forgeries of passports, ID cards, and bank notes. The authenticity of the paper and ink materials and the identification of the various printing technologies generally indicate if the questioned document is a counterfeit or genuine. However, these techniques allow for studying the homogeneity of the material used across the whole questioned documents and thus to detect potential falsifications.

Beside these aspects, several other types of trace can also be found on documents. Among them, finger marks, if present, can be easily revealed on almost all types of paper; DNA can often be extracted from saliva that could be present on the back of stamps; and the use of electrostatic detection devices allows examiners to reveal latent marks on documents.

## Paper

### Introduction

The forensic examination of paper is aimed primarily to determine its origin, to detect any alteration of the

content of the documents, and, more generally, to look for genuineness of these documents.

### History and Composition

The need for a writing medium has constantly increased alongside the development of writing instruments. Early materials such as stone or animal skins were replaced in Ancient Egypt by a media made by crisscrossing and pressing together sliced strips of stem of Papyrus. In AD 105, paper was invented by Ts'ai Lun in China and completely substituted Papyrus around the tenth century AD.

Paper is made from the pulp of fibers from several origins, such as wood, cotton, linen, or rag. The raw material is first chemically or mechanically treated to break it down to pulp. Then, large quantities of water and other materials are added to the fiber pulp, such as resins, minerals, and dyes or whiteners. This mixture is then spread evenly over a surface and dried. At that stage, the frame of the surface and potential watermarks create identifiable patterns on the paper. Finally, the paper is cut to the required dimension.

### Analytical Methods for Paper Analysis

**Nondestructive tests** The operations conducted during the manufacturing process of paper generate features that can help easily distinguish one paper from another, either by direct observation or with the help of basic measuring tools or optical techniques.

The shape, size, thickness, and the weight of the sheets can be measured. Watermarks, frame patterns, and acquired defects, produced by the manufacturing process, can be observed in transmission and reflected light with or without magnification. These patterns can be mathematically compared by Fourier transform algorithm to discriminate papers.

The optical behavior of papers under filtered light examination and ultraviolet (UV)–visible (or visible–infrared (IR)) luminescence is also an important characteristic that helps to differentiate them. Absorption spectroscopy can be used to measure and compare the color of papers.

**Destructive tests** When possible, other tests can take advantage of removing a small amount of the paper to determine the fiber type, the method of pulping, the dyes, and the inorganic elements in the paper.

In the determination of the fiber type, a portion of the paper is broken using water or dilute acid. This

enables the fibers to be examined individually under a microscope. Thus, different varieties of fibers can be identified.

The elemental composition of the paper can be measured by X-ray fluorescence and by inductively coupled plasma-mass spectrometry (ICP/MS).

Finally, dyes and optical brighteners added in the manufacturing process can be analyzed using thin-layer chromatography, e.g., inks.

## Inks

### Introduction

The examination of ink material may provide evidence of considerable value. The detection of an erased ink may indicate a modification of the original message, and drawing comparisons between different inks may indicate a common origin; and with the help of databases, the brand of the writing instrument of ink entries can be identified. Furthermore, under certain circumstances, the date when inks were placed on documents can be determined.

### History and Composition

Inks were first used thousands of years ago in China as well as in Egypt, Greece, and the Roman Empire. These first inks were based, for centuries, on carbon particles in aqueous solutions. During the Middle Ages, iron-tannin, silver, and gold inks were developed and used, up until the nineteenth century, when the addition of indigo dye gave a blue-black color to the writing lines. Since then synthetic dyes from several chemical families have replaced natural dyes and multiple varieties of inks, of all colors, are used in different kinds of writing instruments. **Table 1** lists

the main components of contemporary writing instruments.

### Analytical Methods for Ink Analysis

**Optical examinations** Nearly every examination of a questioned document begins with nondestructive optical methods. Such indicative examinations are performed under normal lighting conditions with magnification. They allow determining the type of ink that is present in the document – and thus the writing instrument that was used – and help to decide which techniques are best suited for the subsequent analyses. The examinations are usually conducted under filtered lights, in the UV, visible, and IR ranges, using reflection and luminescence techniques, in order to reveal differences between inks, expose chemical erasures, and decipher obliterations.

### Spectroscopic techniques

**UV-visible spectroscopy** UV-visible absorbance microspectrophotometry and microspectrofluorimetry are used as nondestructive methods for analyzing inks directly on paper. They measure, respectively, the absorption and emission spectrum of inks and allow the discrimination of similarly colored inks. Therefore, they are a convenient way to render the comparison of ink colors more objectively than the naked eye.

**Raman spectroscopy** Raman and resonance Raman spectroscopy have also been applied to the analysis of inks on paper. These techniques allow the chemical characterization of the ink but were reported to be lacking in sensitivity and to be highly influenced by fluorescence effects caused by papers. Surface enhanced resonance Raman scattering spectroscopy

**Table 1** Ingredients commonly used in modern writing instruments

Writing instrument	First appearance	Coloring material (%)	Solvent	Others
Fountain pen	Reed: ~2500 BC Goose: ~100 AD	Acid dyes	0.6 –	Dextrin Poly(ethylene) glycol
	Modern form: 1809		3	Phenol
Ballpoint pen	Invention: 1888	Basic dyes	Up to 1950: vegetal or mineral oil	Binders: natural resins, polymers
	Modern form: 1939 Commercial: ~1950	Solvent dyes Phthalocyanine	~50 1950 and later: glycol	Fatty acids
Fiber pen	1962	Acid dyes	2 –	Glycol
Rollerball pen	1968		10	Formamide
Gel pen	1984	Pigments	~8	Glycol

helps avoid these deficiencies and shows promising results for the discrimination of gel pens and black ballpoint pen inks containing crystalline dyes.

**Mass spectroscopy** Field desorption mass spectrometry and secondary ion mass spectrometry allow the analysis of the inks' nonvolatile compounds, such as heavy dyes, which cannot be separated by gas chromatography (GC).

**Infrared spectroscopy** Fourier transform infrared (FTIR) and diffuse reflectance infrared Fourier transform spectroscopy have been reported for analyzing organic components of inks, such as resins.

**X-ray spectroscopy** Finally, X-ray fluorescence can be used to determine the elemental profile of inks and papers. Some techniques based on X-ray properties (particle-induced X-ray emission and inductively coupled plasma atomic emission spectroscopy) have been applied to writing inks. Nevertheless, it was found that there were not enough variation between the different particles, present in ink formula, to help distinguish from each other.

**Chromatographic techniques** Contrary to other areas of analytical chemistry, the determination of the absolute chemical composition of inks is not the overarching goal of forensic science. It is rather to determine if two samples are, or not, similar and thus if they are of a potential common origin. Therefore, chromatography is used to separate the components of ink mixtures in order to compare them one by one.

**Planar chromatography** The introduction of chromatographic methods for ink comparisons has been slow, due largely to the reluctance of the courts to accept 'destructive' techniques. Thanks to the improving sensitivity of planar chromatography techniques, starting with paper chromatography, followed by thin-layer chromatography (TLC) and, currently, with the use of high-performance thin-layer chromatography (HPTLC), the removal of small amounts of ink material has become accepted in practice.

HPTLC remains one of the most powerful techniques for the comparison and identification of inks in forensic science. Its advantages have been clearly established: it is cheap, user friendly, expedient, well reported, and tested. Overall, it is a screening technique that is only slightly dependent on the different chemical families of the several dyes included in the composition of each ink. Therefore, it remains the most widely used chromatographic technique for this purpose (see Figure 1).

**Figure 1** Separation of ink's colored material by high-performance thin-layer chromatography. Tracks 1, 9, and 18 are reference dyes' ladders; tracks 2–8 and 10–15 are ink samples; track 16 is a blank paper extraction, track 17 is an extractor blank.

A typical procedure for TLC/HPTLC analysis of inks is as follows. A sample of an ink line, of ~10 mm, is scraped from the document and dissolved in 10 µl of an appropriate solvent in a glass capillary (the extraction procedure can be accelerated by heating the capillary at 100°C for 15 min). The sample is spotted on a preconditioned or pre-washed silica plate and eluted with a solvent. Several mobile phases can be used, depending on the kind of writing instrument examined.

Control samples from alleged sources, or reference samples from databases, are usually run simultaneously with the questioned sample. The compositions of the samples are then compared visually, directly on the silica plate.

The position and color of the inks' various dyes on the silica plates can be measured with a densitometer, while their chemical composition can be determined using a Raman or FTIR spectrometer. The resulting data provide a more rigorous comparison of the inks and allow the storage of the ink profiles in databases.

Sometimes, differences between the obtained analytical results of two inks can occur, even if the two considered inks have a common origin. These differences can be explained under certain circumstances by the storage condition of the document, prior to the analysis. For example, the age of the samples has been shown to decrease the extraction efficiency and the exposure to sunlight has been shown to degrade certain dyes. The interpretation of such differences is often left to the judgment of an experienced forensic scientist, although some computer expert systems have actually been developed.

Finally, it should be noted that these properties, regarding extraction efficiency and dye degradation, are used in some cases for determining the date of the entry's creation.

**Liquid chromatography and capillary electrophoresis** Despite the advantages of HPTLC, many scientists have felt the need for an analytical technique that would offer more sensitivity, with a greater resolution, and a better reproducibility of the analyses.

Researches, done with modern liquid chromatography (LC) and capillary electrophoresis (CE), have demonstrated several advantages over planar chromatography techniques. First, there is the possibility of adding several types of detectors to characterize the components, separated by the analytical technique, such as diode array detector or mass spectrometry. Second, the use of these techniques allows overcoming one of the major disadvantages of planar chromatography, by improving the reproducibility.

However, the choice of the LC method that should be used for the analysis of a questioned dye has shown to be very dependent on the chemical families of dyes that are effectively present in a particular ink (for example, it appears that phthalocyanine dyes cannot be analyzed with the same solvent system and column as solvent dyes). LC analyses are also very time consuming and require a large quantity of solvent.

Despite the ecological advantages over LC (use of aqueous buffer instead of organic solvents), the efficiency of CE compared to LC is still a matter of discussion at this time.

*Gas chromatography* Heavy colored compounds of inks cannot be separated by GC. Therefore, this technique has mostly been used for the quantitative analysis of volatile solvents in inks. Such works are described in paper dealing with the determination of the age of ink entries, based on the relative speed of solvent evaporation.

## Toner Analysis

### Introduction

Due to the widespread availability of business machines over the past 30 years, the forensic document examiner is more than ever faced with the obligation of analyzing toner printed documents. The increasing popularity and quality of black and white and color copiers, laser printers, and fax (facsimile) machines that use toners, has led to a parallel expansion of the use of such systems in criminal activities. The purpose of this article is to point out how the analysis and differentiation of toner, employed in an office machine, can help establish the origin of a printed document or can be used to distinguish printed documents from different sources.

This article will cover only the analysis of the toner itself, in particular the analysis of the black toner. The examination of manufactured identifying characteristics, such as grip marks, roller marks, and acquired identifying characteristics, such as trash

marks or repetitive defects, will be not discussed here.

In this article the term document refers to a document produced by an electrophotographic process (for example, a photocopier, a laser printer, or a Fax machine employing a toner).

### Why do Toner Analysis?

1. To determine if two or more documents were printed with the same toner.
2. To determine if a certain photocopied document is a fraudulent alteration of an original document.
3. To determine the possible make and model of a photocopier that was used to produce a given photocopied document.

### General Theory

A toner can be defined as a material capable of accepting an electrical charge that is used in the general process called electrophotography to create an image (i.e., the printed document). The detailed explanation of the electrophotography process can be found in the specialized literature. It is not the purpose of this article to delve into this process.

### Types of Toners Encountered

Toner can be either dry or liquid. Dry toners are composed of microscopic dry particles ( $\sim 6\text{--}20\text{ }\mu\text{m}$ ) of polymer, additives, and carbon black (or other pigments or dyes), used to create the copy images. A dry toner has a raised, glossy appearance on paper and can be scraped off with a scalpel. Dry toners can either be of single component or a dual component. Single-component toners can be subdivided into magnetic and nonmagnetic toners. Magnetic toners are particularly common for single-color printing with dark colors. Nonmagnetic single-component toners are mostly used in systems functioning at a low operating speed. Magnetic single-component toners contain a magnetic carrier material (magnetite and ferrite are common) that can be detected on the final document. In dual-component toners the carrier (glass or plastic beads) is added separately and recovered afterward; therefore, it cannot be detected on the final copy.

Liquid toners are characterized by carbon black particles (size  $\sim <2\text{ }\mu\text{m}$ ) or dyes, and sometimes polymers, which are suspended in a liquid carrier used to create the images. Liquid toners appear to dye the individual paper fibers. Liquid toners are often encountered in the so-called Indigo process.

Table 2 lists some common ingredients found in modern dry toners.

**Table 2** Ingredients commonly used in single- and dual-component dry toners

Single component (%)	Ingredient	Example	Two component (%)
45–60	Binding agent, polymer	Styrene/acrylate copolymer, polymethacrylate resin, polyester, etc.	2–5
	Pigment	Carbon black, Prussian blue, various organic pigments	
	Additive	Fused silica	
40–55	Carrier	Spherical ferrite	95–98
	Magnetic pigment	Magnetite, ferrite, or maghemite	

### Analytical Methods for Toners

**Optical microscopy** Dry and liquid toners can be distinguished by observation under low power magnification ( $\sim 20\times$ ) using a binocular stereomicroscope. If distinct particles of the toner can be observed, then it is a dry toner. Dry toners have a raised, often glossy appearance, and can be scraped off the page with a scalpel blade. In some instances, the morphological aspect of the dry toner can be easily distinguished, by observing the document with an angled or a transmitted illumination.

Liquid toners penetrate into paper fibers and appear as a thin coating through which paper fibers can be seen quite unmistakably. Liquid toner copies can sometimes be mistaken for documents produced by other forms of printing (for example, an ink jet printer or an inked stamp). Microscopic examinations, at a magnification of  $100\times$ , can also discriminate the toner's methods of fusion with the paper substrate.

While this is a highly discriminatory technique, it is also difficult to apply, and great prudence should be exercised in its employment. The differences between the fusion methods are slight and it can be difficult to appreciate them unless the observer has great familiarity with toner examination. The best way of acquiring the right know-how is to examine numerous documents produced on machines utilizing well-known fusion methods.

**Optoelectronics systems** Single-component toner powders, which contain magnetic material, incorporated into the toner particles when fixed onto the paper, exhibit magnetic properties similar to other forms of magnetic printing. The magnetic properties can be elegantly detected using an optoelectronic system and allows differentiating magnetic single-component toners from dual-component toners.

**Scanning electron microscopy (SEM)** It can be applied to acquire comprehensive information on the surface morphology of toner samples, which can be

used as a resource to differentiate toners. Very small samples (1 mm diameter) of toner bearing paper are isolated from a document using a proper cutting instrument. Samples are then fixed on an SEM holder with a double-sided adhesive tape and then coated with carbon, gold, platinum, palladium, or silver; the choice of the coating depends on the type of analysis conducted. Three photographs of each sample are recorded, using an enlargement of  $500\times$ , which is found to be the most valuable single magnification for observing the surface morphology. The basic method of toner fusion (liquid toner, dry toner with heat fusing, dry toner with cold pressure fusing, and dry toner with combined heat and pressure fusing) on plain paper may be determined by SEM.

**Scanning electron microscopy coupled with energy dispersive X-ray (EDX) microanalysis** X-ray microprobe analysis provides information on the inorganic content of the toner and allows to characterize elemental data for elements of atomic numbers from boron ( $Z = 5$ ) to uranium ( $Z = 92$ ). Samples are prepared and examined by the scanning electron microscope, using the same method as that of surface morphology examination. This method may confirm the detection of magnetic material and easily distinguishes single-component toners from dual-component toners.

Single-component toners are further divided according to the type of magnetic material present (i.e., maghemite, magnetite, or ferrite). Additional differentiations can be carried out according to the minor constituents present and their relative proportions. Dual-component toners do not contain significant quantities of mineral compounds, although some may show traces of iron. The latter may be explained as an incomplete separation of the two components allowing some traces of the carrier material to be found on the paper.

In general, SEM–EDX toner analysis can highlight the presence of the following mineral elements: Ca, Cl, Cr, Cu, Fe, Mn, Ni, S, Si, Sr, and Zn. It must be stressed that a paper blank must always be

examined. Some papers have a high inorganic content, due to the fillers used, and often the inorganic content of the paper substrate itself, is reflected in a spectrum thought to derive from the toner. Due to the heterogeneity of the paper and toner, in combination with the minute area of analysis, multiple sampling and analysis are strongly recommended. This can be facilitated using models of environmental scanning electron microscopes that have a larger specimen chamber where it is possible to examine, in a nondestructive manner, an A4-size document.

### Spectroscopic examinations

**Color measurement** In the case of colored toners, UV and visible (UV-Vis) transmission spectroscopy is successfully applied. If an isolated toner particle of cyan, magenta, yellow, and black is available on a document, the problem of color separation is irrelevant. However, in routine cases, color separation must be practiced under a microscope. The various colored toner particles, composing a colored image, are isolated, embedded in glycerin, and placed on a quartz slide. The UV-Vis spectra are measured using a microspectrophotometer that provides a more objective measure of colors, compared to the subjective evaluation of the naked eye or the use of an optical microscope alone.

**Fourier transform infrared analysis** FTIR spectroscopy is a suitable method for the differentiation of the organic binders present in toners. Many different techniques can be applied for analyzing toners using IR spectrometry. The analysis of toners may be effectively performed by microscopic attenuated total reflectance, with an internal reflection element (germanium crystal, for example) or by diffuse reflectance (DR) microscopic reflection-absorption techniques that have a diversity of reflecting media including mirrored slides, low sensitivity glass, metal disks, and aluminum foil, and transmittance. The choice of an analytical technique can be made based on equipment accessibility, ease of sample preparation, speed of analysis, and the kind of damage that may be done to the original document.

### Chromatographic examinations

**Thin-layer chromatography** Dye as well as binder components of photocopy toners may be analyzed with the help of TLC.

**Pyrolysis gas chromatography mass spectrometry** Pyrolysis gas chromatography, combined predominantly with mass spectrometry, is a powerful analytical method for the categorization of polymers. Moreover, it is useful for the characterization of

monomers, comonomers, additives, and impurities. During pyrolysis, which is usually performed at  $\sim 700^{\circ}\text{C}$ , large molecules are broken up into smaller ones which are then separated by GC and detected by MS. Pyrolysis GC-MS is a highly discriminatory method of analysis, which is quite time consuming and has a limited reproducibility.

**Laser microprobe gas chromatography-mass spectrometry** A laser microprobe is used to target selectively microscopic samples of toner, for subsequently GC-MS detection. Fused toners are directly analyzed *in situ* avoiding the traditional separation of toner from the paper substrate. This method offers a high spatial resolution and selectivity but further studies may be necessary to improve its reproducibility.

### Miscellaneous examinations

**Differential scanning calorimetry** A brief study using differential scanning calorimetry showed potential usefulness for thermal analysis but was not pursued due to the time-consuming nature of the technique.

### Interpretation of Toners Comparison

Forensic laboratories have established databases of toner composition used by electrophotographic devices. Maintenance of such a database requires tremendous labor. There are few manufacturers of toner but there are many formulations composed by each manufacturer. To complicate matters further, toners and gray toners manufactured with nonoriginal equipments do not always have the same chemical composition as original ones. For these reasons, the analysis of toner is most useful to determine whether or not two or more documents were printed with the same toner.

### Introduction

One of the main activities in a forensic chemical laboratory is the examination of powders, pills, and plant materials thought to be illicit or controlled substances. The analysis of suspected drugs of abuse occurs over a number of stages. These involve the preparation of the analytical space within the laboratory, a physical examination of the item including its packaging, the use of a sampling protocol depending on the nature of the samples presented and the analysis required and the analysis of the sample. There are various analytical techniques commonly used in the forensic examination of suspected drugs and these include presumptive testing (color/spot tests), thin layer chromatography (TLC), liquid chromatography (LC), gas chromatography (GC) with either flame ionization detection (FID) or mass spectrometry (MS), Fourier transform infrared spectroscopy (FTIR), and ultraviolet (UV) spectroscopy. In many situations the data obtained from these analyses would then be compared with laboratory reference standards and/or a standard reference text such as Clarke's analysis of drugs and poisons.

The choice of technique which is used, depends upon the requirements of the analysis and specifically

the questions and hypothesis to be addressed. Specifically this commonly includes:

- **dmac\_aq>p0015**Determination of the identification or confirmation of the presence of a controlled substance in a sample;
- **qmac\_aq>p0020**Quantification of any controlled substance (i.e., determining the amount of the controlled substance present); and
- determination of links between samples or synthetic route used in sample production through chemical profiling or characterization of synthetic by-products and/or reaction impurities within the sample.

### Legal Aspects of Illicit Drug Analysis

The United Nations through their office on drugs and crime (UNODC) has produced over the years three major international drug control treaties, which are mutually supportive and complementary. In addition to including general provisions on illicit trafficking and drug abuse, they seek to ensure the availability of narcotic drugs and psychotropic substances for medical and scientific purposes and to prevent their diversion into illicit channels.

The treaties are:

- Single Convention on Narcotic Drugs, 1961 as amended by the 1971 Protocol concerning psychotropic compounds.

- Brandi J, James B, and Gutowski SJ (1997) Differentiation and classification of photocopier toners. *International Journal of Forensic Document Examiners* 3(4): 324–343.
- Cantu AA (1995) A sketch of analytical methods for document dating part I. The static approach: determining age independent analytical profiles. *International Journal of Forensic Document Examiners* 1(1): 40–51.
- Cantu AA (1996) A sketch of analytical methods for document dating part II. The dynamic approach: determining age dependent analytical profiles. *International Journal of Forensic Document Examiners* 2(3): 192–208.

### Introduction

One of the main activities in a forensic chemical laboratory is the examination of powders, pills, and plant materials thought to be illicit or controlled substances. The analysis of suspected drugs of abuse occurs over a number of stages. These involve the preparation of the analytical space within the laboratory, a physical examination of the item including its packaging, the use of a sampling protocol depending on the nature of the samples presented and the analysis required and the analysis of the sample. There are various analytical techniques commonly used in the forensic examination of suspected drugs and these include presumptive testing (color/spot tests), thin layer chromatography (TLC), liquid chromatography (LC), gas chromatography (GC) with either flame ionization detection (FID) or mass spectrometry (MS), Fourier transform infrared spectroscopy (FTIR), and ultraviolet (UV) spectroscopy. In many situations the data obtained from these analyses would then be compared with laboratory reference standards and/or a standard reference text such as Clarke's analysis of drugs and poisons.

The choice of technique which is used, depends upon the requirements of the analysis and specifically

the questions and hypothesis to be addressed. Specifically this commonly includes:

- **dmac\_aq>p0015**Determination of the identification or confirmation of the presence of a controlled substance in a sample;
- **qmac\_aq>p0020**Quantification of any controlled substance (i.e., determining the amount of the controlled substance present); and
- determination of links between samples or synthetic route used in sample production through chemical profiling or characterization of synthetic by-products and/or reaction impurities within the sample.

### Legal Aspects of Illicit Drug Analysis

The United Nations through their office on drugs and crime (UNODC) has produced over the years three major international drug control treaties, which are mutually supportive and complementary. In addition to including general provisions on illicit trafficking and drug abuse, they seek to ensure the availability of narcotic drugs and psychotropic substances for medical and scientific purposes and to prevent their diversion into illicit channels.

The treaties are:

- Single Convention on Narcotic Drugs, 1961 as amended by the 1971 Protocol concerning psychotropic compounds.

- United Nations Convention against the Illicit Traffic in Narcotic Drugs and Psychotropic Substances, 1988.

The UNODC's Legal Advisory Programme promotes adoption and practical implementation of these conventions. It addresses the needs of States that have outdated drug control legislation, are most vulnerable to criminal activity, or lack success in major prosecution and asset forfeiture casework. The program advises states on the drafting, adoption, and application of all necessary legislation.

Each country generally has its own drug legislation, which in general has undergone some evolution over the years. A comprehensive list of the different legislative controls are to be found on the United Nations web site at the following URL: [http://www.unodc.org/unodc/legal\\_library/index-countries.html](http://www.unodc.org/unodc/legal_library/index-countries.html).

## Laboratory Examination

### Preparation of the Analytical Space

One of the most important (and fundamental) parts of the examination of samples suspected of containing controlled substances is the initial preparation of the space where the analysis is to take place. Benches should be washed down with detergent, dried, and then swabbed with methanol or similar solvent. The swabs should be retained for analysis if required. Fresh bench covering should be laid on the bench. Sample packages should be opened individually and the bench should be cleaned as described, in between subsequent packages being opened. There should be frequent changes of gloves and meticulous notes require to be kept on all procedures undertaken.

## Physical Examination

### Packaging

Once drug samples are presented for examination, their packaging should be checked to ensure that it is intact. Any breach of the packaging should be reported and a decision taken as to whether the analysis of that item should be continued. Packaging materials for drug samples come in a variety of forms, from wrapping materials such as cling film (often around cannabis resin), tin, or aluminum foil (powder samples and some tablets) to larger polyethylene bags ranging from bank bags to bigger ziplock type bags. In some cases linkages can be made from sample to sample based upon the packaging materials present and it is well worth spending time on their

examination. For example, cling film can be physically linked using polarized light techniques and chemically linked using FTIR.

### Samples

The physical description of an item, as well as the types of analysis undertaken, will depend upon whether that item is considered a bulk or trace sample. Each item should be described fully (with diagrams if appropriate) including a description of color, smell, and any packaging materials, which may be present. If there are logos (ecstasy tablets) or marks on the items (blocks of resin or packages of drugs), these should be fully described and possibly photographed. Microscopic examination may also be used to examine the morphological characteristics of the material. This includes descriptions of different types of crystals or other solids, which may be present, the structure of tablets, the presence of different botanical features in seizures of plant materials.

**Trace versus bulk samples** A trace sample is considered to be one, which is barely visible to the naked eye. Samples such as this will be present on the insides of reaction vessels, scales, knives, and other drug paraphernalia. In many cases, trace samples are swabbed from these items and are analyzed using confirmatory techniques first. Such samples are very easily contaminated and significant care should be taken in their analysis. Bulk samples require a sampling methodology and are generally subjected to presumptive tests and TLC followed by confirmatory tests.

## Sampling Protocols

Many laboratories have developed their own sampling protocol for drug samples. In all cases, samples should be taken from items, which have the same morphology (also called sampling by attributes). This means that if a seizure is found to contain different types of materials, then each type should be sampled separately. This is particularly true for samples containing tablets with different logos or of different colors, or items, which have been packaged separately from each other. Where blocks of resin are being sampled, this should be away from the edges of the block as such edges can potentially be used to make physical fits between the blocks. In cases where samples of powder are seized, it is necessary to ensure that the powder is homogenous which is generally accomplished using standard techniques.

Two things generally dictate sampling protocols:

- A legal obligation which may require that all items in a seizure are described and sampled.

- A policy left to the expert, which will include a description of the items and the selection of a sample from the items.

The criteria for selecting the type of sampling protocol undertaken should include a balance between the loss of completeness versus time saving.

In actual fact most sampling protocols are based upon a mathematical distribution called the hypergeometric distribution (eqn [1]). Some laboratories have adopted this as their sampling policy and will only analyze a maximum number of samples or packages from any one seizure regardless of the total seizure size. The number analyzed varies depending on the level of accuracy (99%, 95%, etc.) which is acceptable.

$$P(m/n, M, N) = \frac{{}^M C_m ({}^{N-M} C_{n-m})}{{}^N C_n} \quad [1]$$

where

$${}^a C_b = \frac{a!}{(a-b)!(b!)}$$

and  $n$  is the size of the subpopulation analyzed,  $m$  a desired outcome,  $N$  the size of the sample, and  $M$  the number of positive outcomes in the sample.

An international system of sampling, which has been adopted and promoted by the UNDCP is as follows.

#### Powders and Tablets and Packages

- Single package of material – The material should be removed from all packaging and weighed to a constant dry weight. The sample is then homogenized and a sample removed.
- More than one package – The material in each package should be examined by eye for color differences. The contents of each package should be weighed (cleaning balance in between each weighing) and each package should be tested using a color spot test or TLC. If it is assumed that all packages contain the same material then;

if there are less than 10 packages all should be tested

if there are between 10 and 100 packages 10 should be tested at random

if there are more than 100 packages the square root of the total should be tested at random.

#### Liquids

If all of one phase then a sample of the liquid is removed for testing. If there are more than one phase

present then a sample of each phase should be removed for testing.

## Identification and Quantification Techniques

### Presumptive Tests – Identification of Drug Class

The first tests carried out on a sample are presumptive tests to give an indication of the class of drug which may be present in the sample. These are generally performed on clean porcelain tiles, in solution or on adsorbent substrates. The most common type of presumptive test involves the addition of various reagents to the sample to produce a color. Other tests involve the use of microscopy to identify trichomes in suspected cannabis samples or microcrystalline tests where the formation of specific crystals is indicative of the class of drug present. In all cases appropriate positive and negative control samples must be used. Table 1 lists some of the results obtained with different spot test reagents for common drugs of abuse.

**Advantages and disadvantages of presumptive tests** Most presumptive tests are carried out on porcelain tiles. There are a number of clear advantages to tests of this nature: they are cheap, quick, and easy to use. They also have the advantage of being portable if required and various ‘road side’ test kits have been developed on the basis of color tests.

The main disadvantages are that the colors formed are subjective, may change over time, and may be produced by more than one drug compound or by compounds other than controlled substances. These tests are also of limited sensitivity (few micrograms) and so are often not suitable for the analysis of trace samples.

### Thin Layer Chromatography – Identification of Drugs within a Class

Having tentatively identified the class or classes to which the drug belongs to using presumptive testing, the next stage in drug identification is to examine which types of drugs from the class are present in the seizure. This can be achieved using TLC, a technique which has the advantages of being both rapid and cheap. The separation process depends on the relative strength of interaction of the sample components with a stationary phase, and a solvent moving through this material, the mobile phase. The solvent in which the sample is dissolved must be one that is suitable for the analysis of the suspected compound.

**Table 1** Expected color reactions for the most common drug compounds

Test	Drug									
	Opiates	Amphet.	Cocaine	Cannabis	LSD	Barb.	Benzo.	Mescaline	Methaqualone mecoqualone	Psilocin psilocybn
Marquis	Purple/violet	Brown/orange/green								
Mandelin	Red/brown	Green	Orange			Slight green	Pink/yellow	Orange/red		Green/brown
Duquenois-Levine				Violet						
Dille-Koppanyi						Red/purple				
Zimmermann							Red/purple/yellow			
Vitali-Morin							Yellow			
Cobalt thiocyanate							Blue (slow)			
Ehrlich			Blue		Blue/violet			Blue		Grey/brown
Simon		Red/brown								
Fast Blue B				Red/purple						

**Suitable solvents** Suitable solvents for drug analysis are ones where the drug of interest is freely soluble and the solvent does not react with the drug or catalyze drug breakdown. The solvent should also be volatile and water free to allow for easy concentration of the sample. The sample to be analyzed together with positive and negative (solvent only) controls should all be spotted onto the same TLC plate and developed in the usual manner.

After development the plate is viewed under UV light and any spots present are marked. Other visualization techniques are commonly used and different classes of drugs require different techniques usually involving spraying the plates with various reagents (Table 2).  $R_f$  values are determined and compared with the controls run on the same plate and may be compared with literature values (though these should be interpreted with care). In the case of trace samples, the samples are swabbed using a buccal swab. The swab is first extracted (rinsed) with a solvent suitable for the analysis. The solvent is concentrated under nitrogen and analyzed for the presence of drugs. The swab is then rubbed over the surface of the item thought to contain the trace drug, the head cut off and extracted with solvent, and the extract concentrated under nitrogen and analyzed. The swab head and concentrated extract should be refrigerated and retained.

Despite being relatively cheap, rapid, and easy to interpret, TLC has a number of disadvantages which include:

- lack of resolution;
- lack of specificity of spray reagents giving similar color reactions for some compounds of the same class;
- edge effects on the TLC plate;
- variable  $R_f$  values; and
- relatively low sensitivity.

### Chromatographic Methods used as Confirmatory Techniques

Having identified the drug class and perhaps the drug within that class, the next stage of the analytical procedure is to confirm the identity of any drug present. Instrumental techniques are used to accomplish this and these can be either chromatographic or spectroscopic. Such techniques provide much stronger evidence than noninstrumental techniques.

Chromatographic techniques identify drugs through their physical and chemical properties of the molecule as a whole such as structure and size, whereas spectroscopic tend to identify compounds on the basis of certain parts present within the molecule. Instrumental techniques are used not only in

**Table 2** Some suggested TLC systems and visualization reagents for different drug compounds

<i>Drug</i>	<i>TLC mobile phase</i>	<i>Visualization reagent</i>	<i>Result</i>
LSD	Chloroform/methanol (9:1 v/v)	1. UV at 254 nm 2. UV at 360 nm 3. Ehrlich's reagent	Absorbs Fluorescence Blue/purple
Opiates	1. Ethylacetate/methanol/ammonia (85:10:5 v/v) 2. Chloroform/methanol (9:1 v/v)	1. UV at 254 nm	Absorbs
Amphetamines	Methanol/ammonia (100:1.5 v/v)	2. Acidified iodoplatinate 3. Dragendorff solution 1. Ninhydrin reagent and heat at 115°C 2. Result of 1 + acidified iodoplatinate 3. 0.5 mol l <sup>-1</sup> NaOH + 0.5% Fast black K	Blue/purple Orange Violet/pink Gray/violet/brown Brown/pink/red
Barbiturates	1. Ethylacetate/methanol/25% ammonia (85:10:5 v/v) 2. Chloroform/acetone (80:20 v/v)	1. UV at 254 nm	Absorbs
Cocaine	Methanol/25% ammonia (100:1.5 v/v)	2. Mercury(II) chloride–diphenylcarbazon	Blue/pink
Mescaline/ psilocin	Methanol/ammonia (100:1.5 v/v)	Acidified iodoplatinate 1. UV at 254 nm  2. Fluorescamine reagent 3. Ninhydrin reagent and heat at 120°C	Absorbs  Bright at 365 nm Violet

confirming the identity of a drug, which may be present but also in quantification (determining the concentration) of the drug which may be present.

### Liquid Chromatography of Drugs of Abuse

LC is a technique used commonly to identify and quantify drugs of abuse. The technique has a number of advantages and disadvantages specific to drug analysis.

Advantages:

- it is nondestructive and samples can be recovered if required;
- the analyte does not need to be volatile;
- the sample generally does not require pretreatment such as chemical derivatization;
- the analysis can be automated; and
- quantification can be achieved without the necessity of an internal standard.

Disadvantages:

- the analyte needs to have properties which can be detected in a liquid stream;
- in most cases a UV or diode array detector and so the analyte needs to possess chromophores;
- the sample needs to be soluble in a wide range of solvents;
- quantification can be slow; and
- large volume of solvents are used.

In general a mixture of reverse-phase and straight-phase systems are used depending on the drug under

test. LC analysis is particularly used where quantification of the target drug is required as the system can be run without the use of an internal standard. Difficulties arise in complex mixtures of street drugs where reaction by-products and impurities as well as additives can cause complications within the chromatogram. As in any forensic examination, the injection sequence for samples is of importance. Calibration standards and samples should always be interspersed by blank injections to ensure cleanliness of the instrument.

### Gas Chromatography

GC has advantages and disadvantages as a confirmatory technique when compared to LC. The GC system has a greater resolving power than LC systems and does not have the same problems associated with mobile phase choice or require large volumes of solvents. However, GC does require the compound to be thermally stable, volatile, and exhibit good chromatographic qualities. This often requires derivatization of the compounds.

### Chemical Derivatization of Some Drugs

Many drugs can be chromatographed using GC directly; however, a number of compounds may give rise to problems such as thermal decomposition (cannabinoids and cocaine alkaloids), reactions within the instrument between compounds in the injected mixture (morphine), adsorption, or coelution. In order to improve chromatographic results some drug compounds require derivatization where  $-OH$ ,

–NH<sub>2</sub>, and –COOH groups are modified. The choice of derivatization reagent depends upon the types of functional groups present. Derivatization alters the chemical structure of the compound to a certain degree, which will in turn influence the results of any subsequent mass spectra produced. There are some common derivatization reagents in use:

1. *N,O*-bistrimethylsilylic acid (BSA) is commonly used to derivatize cannabinoids, opiates and cocaine analogs (ecognine, etc., cocaine shows good chromatography).
2. *N,O*-bistrimethylsilyltrifluoroacetamide (BSTFA) is commonly used to derivatize LSD and psilocybin.
3. Trifluoroacetic anhydride (TFAA) and heptabutylr anhydride (HFBA) are commonly used to derivatize amphetamines.

GC and LC provide a means of separating the components of a complex mixture but neither technique can definitively identify any component. More than one component may have the same retention time for a given system or may have chromophores, which are difficult to differentiate. For this reason it is generally accepted that two (preferably three) independent techniques are used to identify the compounds present. The generation of UV absorption spectra using diode array detection (DAD) can help accomplish this in LC analysis though many compounds have similar UV spectra. In GC analysis, the system can be coupled to a mass spectrometer and a mass fragmentation pattern produced for each compound, which can be used to identify the compound together with the chromatographic data.

GC–FID is often used in drug analysis but increasingly routine is the use of GC–MS. In this case the GC is interfaced with a mass spectrometer detector (MSD). This can be either in place of a conventional detection system such as an FID or in tandem with an existing detector. When using an MSD the carrier gas is generally helium, which has low molecular weight (does not contribute to observed ion signal) and which is oxygen and water free.

The information derived from GC–MS includes retention time and the mass spectrum of each eluted peak. Principal peaks are used in the identification of unknown compounds where these are the peaks of the most intense ions (usually 6–8 peaks). These can be compared to reference data in an attempt to identify the compounds.

**Selective ion monitoring** If a drug sample being analyzed is complex, it may be difficult to obtain baseline resolution for the different components of

the mixture. Selective ion monitoring essentially means setting the mass spectrometer to examine the mass spectra produced for a particular ion peak or set of peaks. The total ion chromatogram (TIC) can then be scrutinized for the presence of these peaks. This method can be problematic. The selected ions only form a small part of the total ion count. If the sample is weak then the selected ions may not be visible against the background noise. Secondly ions chosen must be characteristic of the compound in question.

**General comments** Quantification can be carried out using a GC–MS (or a GC–MS with FID detector) either by using the internal standard technique or using a deuterated homolog (compound of similar structure) as the compound under test. Generally the methyl group attached to a nitrogen moiety or functional groups attached to the main structure are those which are deuterated. The replacement of hydrogen atoms in this manner alters their mass from 1 to 2, thus causing different fragmentation patterns. This removes the necessity for baseline resolution of the target peak and its deuterated internal standard. Quantification is determined using the ratio of the peak heights (or areas) of the specific ions within the mass spectrometer.

### Spectroscopic Techniques

**Fourier transform infrared spectroscopy** FTIR is an extremely useful technique for confirming the identity of pure compounds, but has limited value if used for mixtures of compounds. The technique is based upon the identification of functional groups within molecules where such groups vibrate (either through stretching or bending in various ways) when irradiated with specific wavelengths of light. These vibrations and their intensity (% transmission) are plotted against the frequency of light (cm<sup>–1</sup>) to which the sample is exposed to produce an FTIR spectrum. Portions of the FTIR spectrum are unique to the compound under test (this is called the fingerprint region). Unfortunately, because the majority of seized samples are mixtures of compounds, FTIR has limited practical use in the analysis of street samples of drugs of abuse. However, it does have the advantages of being nondestructive and not requiring derivatization.

**Ultraviolet–visible (UV–Vis) spectroscopy** UV–Vis spectroscopy, like FTIR, is a technique which is useful in the identification of pure drug compounds. Different compounds contain chromophores, which will absorb specific wavelengths of UV or visible

light. The technique obeys the Beer–Lambert law and as such the absorption of spectra generated at given wavelengths have the added advantage of being directly related to the concentration of the sample (this is the basis of the diode array detector used in LC). Normally UV and UV–Vis spectra are recorded at high and low pH and the results of both for the sample under question compared with known standards.

UV–Vis is a cheap and easy technique, which allows sample recovery and good discrimination between pure compounds without the need for derivatization. It has less application for street samples involving complex mixtures.

## Which Instrumental Technique to Use?

The choice of instrumental technique used in any analysis depends upon the motive behind the analysis and on the nature of the sample. Normal procedure when dealing with bulk samples is to perform presumptive color tests to identify the drug class followed by TLC to identify the specific member of the drug class. When dealing with trace samples, it is often the case that these nonconfirmatory tests are circumvented and confirmatory tests only are employed. The choice of confirmatory test now depends on the motive behind the analysis as indicated below. The choice of technique will also depend upon the nature of the analytes under investigation.

For example, large compounds such as the cannabinoids are not particularly thermally labile and benefit for derivatization, however, this has implications in drug profiling as derivatization results in altering the chemical structure. LC analysis of cannabinoids will effect their identification but difficulties in resolution may hamper quantification and profiling. In practice many laboratories now identify cannabis on the basis of microscopy rather than instrumental techniques.

Samples thought to contain heroin require derivatization to help resolve some of the components though diamorphine itself chromatographs well without derivatization. Introduction into the GC system causes acetylation of morphine and monoacetyl morphine thus inflating the concentration of diamorphine above the actual value if GC is used as the quantifying technique. Heroin samples are generally profiled using a GC/MS system.

Amphetamine compounds are generally easily analyzed using either GC or LC and are profiled using a GC/MS system. LC is useful for quantification though a common diluent, caffeine has a significantly different molar extinction coefficient than

the amphetamines causing a large peak on the chromatogram, which may cause coelution problems. There are also coelution problems with some of the structurally similar compounds.

Barbiturates and benzodiazepines are difficult to analyze both by GC and LC. In GC analysis, barbiturates are derivatized on column by the addition of  $0.2 \text{ mol l}^{-1}$  trimethylanilium hydroxide in methanol and concentrating the solution using  $\text{N}_2$ . The sample is injected into GC where and alkylation reaction takes place. The sample retention is governed by the length of carbon chain at the C-5 position and the degree of polarity of the molecule. In general as the carbon chain length increases, so does the lipophilicity and consequently the retention time. Where chain lengths are the same, the degree of polarity becomes the deciding factor with more polar compounds eluting earlier.

## Data Interpretation

There are a number of mathematical techniques commonly used with data obtained from instrumental techniques. These enable the verification of the instrumental analysis with respect to reliability and reproducibility of response, comparison of retention time data, and the determination of the concentration of active component (to greater or lesser degrees of accuracy and with slight variation depending on the type of analytical technique used).

### Relative Retention Time

The relative retention time (RRT) is often calculated for peaks in chromatograms particularly when its identity is unknown. This can be compared to other sample data or data generated using standards or from a database generated under the same chromatographic conditions. An internal standard is added to the test solution and the following equation is used. RRT values can be calculated for both GC and HPLC analysis:

$$\begin{aligned} \text{Relative retention time} \\ &= \frac{\text{Retention time for analyte}}{\text{Retention time for internal standard}} \quad [2] \end{aligned}$$

It is important to be able to measure the reliability and reproducibility of analysis. This is usually conducted on a daily or more often weekly basis by analyzing standard samples. Both repeat injections of the same standard (showing instrumental variation) and different samples of the same standard (showing extraction and sample variation) and apply an appropriate statistical analysis to the results.

### Relative Standard Deviation (Coefficient of Variation)

This is a measure of the standard deviation expressed as a percentage over a number as of analytical results. The relative standard deviation (RSD) value (%) should ideally be as low as possible showing a high analytical reproducibility.

$$RSD = 100 \left( \frac{s}{\bar{x}} \right) \quad [3]$$

## Quantification Techniques

### Single Point Estimates

This method is one of the quickest that can be used, however, an assumption is made that the instrumental response is proportional to the concentration of the analyte under test and that the concentration of the sample is within the linear dynamic range of the detector. One standard solution is analyzed along with the sample and eqn [4] is used to relate their concentrations to each other. Equation [4] illustrates the application for LC analysis; if GC analysis were being carried out each solution would also include an internal standard.

$$\frac{\text{Peak area sample}}{\text{Peak area standard}} = \frac{\text{Concentration of sample}}{\text{Concentration of standard}} \quad [4]$$

$$\frac{\text{Peak area sample}}{\text{Peak area standard}} \times \text{Concentration of standard} = \text{Concentration of sample}$$

### Two-Point Estimates

In this case two standards are analyzed, one of a concentration higher than is expected in the sample and one of a concentration lower than expected.

Again the assumption is made that all measurements are made within the linear range of the detector. The relationships between the different standards and their respective responses are solved as simultaneous equations to determine an equation of the straight line between the points. The concentration of the sample is determined using this equation.

### Regression Analysis

This is by far the most accurate method for quantifying samples. It does not rest on the assumption that the concentrations determined are within the linear range of the detector but rather verifies whether this is correct. The method also involves running repetitive samples of the same standard and as such will take into account variation of detector response. However, the method does require analyzing many samples (at least 2 and preferably 3 data points at five different concentrations) and as such can be time consuming.

## Techniques in Drug Profiling

In the clandestine preparation of illicit drugs, specifically amphetamine and its analogs a number of common synthetic routes are utilized (Figure 1).

As a consequence of this route, specific impurities can be identified in GC analytical traces obtained from submitted samples and these can be used to determine which manufacturing route was utilized as well as in investigating links between illicit samples through impurity profiling.

### Organic Impurity Profiling

At the present time, chemical profiling methods are mainly based on determining and quantifying

**Figure 1** Leuckart synthesis of amphetamine.

organic impurities present in the seizure. In the case of synthetic drugs, some of these impurities and intermediates may be route specific. Techniques such as GC-FID, LC, and FTIR may be employed but perhaps the most beneficial is GC-MS, whereby, the identity of eluted components can be determined from the corresponding mass spectrum. Ultimately, determination of the organic impurities aims to identify common batch links among illicit seizures, while quantification has ramifications in subsequent criminal proceedings. Illegally synthesized drugs may eventually be distributed in more than one country and hence, the need for a universal method to establish links between seizures is apparent. Recent work has focused on the development of computer-based programs to improve the accumulation and appropriate accessibility of drug intelligence data.

Early chemical profiling attempted to establish batch links among illicit drug seizures by comparative studies, based on both qualitative and quantitative information, although success in achieving this has been varied. Such studies have been applied to link heroin and cocaine samples to common origins, based on the concentration of the organic impurities present. Isotopic analysis of impurities and intermediates has been employed in the comparison of seized heroin, methamphetamine, and ecstasy samples. X-ray diffraction and NMR spectroscopy (both  $^1\text{H}$  and  $^{13}\text{C}$ ) have been used to

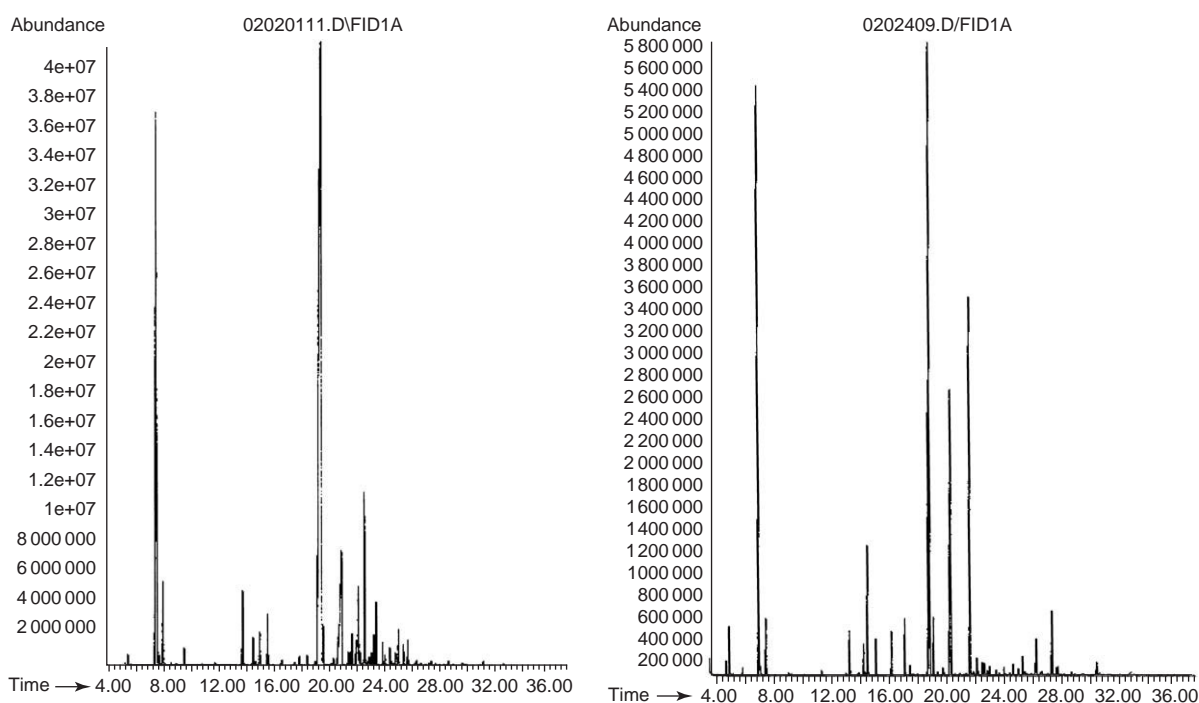

differentiate the origin of illicit ecstasy seizures (Figure 2).

### Inorganic Impurity Profiling

Since 1980, ICP-MS has emerged as a major and powerful technique in the area of elemental analysis. It offers extremely low detection limits which range from sub parts per billion (ppb) to sub parts per trillion. In addition, these detection limits are broadly achieved for almost all the elements across the periodic table. Also, the simple nature of the mass spectra of the elements makes this technique a quick tool for automated qualitative, semiquantitative, and quantitative elemental analysis. Metal content of bulk drug substances may originate from different sources:

- from the plant containing the drug which is then extracted (Poppy, Cannabis, or coca leaf);
- from catalysts, reagents, and solvents used in the extraction and/or syntheses;
- from exposure to air-borne particles;
- from container/closure systems, etc. used in synthesis/extraction.

There exists, therefore, a potential for use of this technique in relation to drug profiling. Moreover, easy sample preparation (powders directly dissolved in dilute nitric acid, with or without help of

**Figure 2** GC-TIC of impurity profiles of two unrelated (street) amphetamine samples.

**Figure 3** HCA of ecstasy tablets indicating linkages between samples.

microwave heating) and quick analysis time (about 2 min per sample) make this technique very attractive for drug profiling.

### Isotope Ratios

Stable isotope analysis is based on the fact that the major elements of organic compounds exist in their naturally occurring isotopic form. The corresponding stable isotope ratios ( $^{18}\text{O}/^{16}\text{O}$ ,  $^{15}\text{N}/^{14}\text{N}$ ,  $^{13}\text{C}/^{12}\text{C}$ , and  $^2\text{H}/^1\text{H}$ ) in natural products depend not only on the biosynthetic pathway but also on the environmental conditions such as humidity or temperature. Consequently, it is possible to use such analyses to determine the geographical origin of natural products. They are already routinely used by many food control laboratories to detect, for instance, addition of foreign sugar in pure fruit juices. For synthetic substances, the isotope ratios are linked to the synthetic conditions (reagents, time, catalysis, etc.) used and to the purification processes, e.g., distillation and it is possible to discriminate between batches of substances. For instance, analgesic drugs such as acetaminophen and aspirin, even manufactured following precise protocols, are significantly heterogeneous in isotopic composition. One advantage of stable isotope analysis is that isotope ratios are intrinsic parameters of the drug substance; therefore, they are not modified by partial degradation or addition of foreign materials during the distribution process.

### Data Analysis in Drug Profiling

The power of chemical profiling has been further enhanced through the application of chemometric procedures to the analytical data generated.

Amphetamine samples have been linked, according to the impurities present, using the Quotient method and a supervised learning method known as SIMCA (soft independent modeling of class analogy), both of which were applied to develop a harmonized method for heroin profiling. Canonical variate analysis has also been used to classify methylamphetamine hydrochloride according to synthetic route, again based on the chemical impurities present and multivariate methods of hierarchical clustering, principal component analysis, and  $k$ -nearest neighbors were utilized to establish batch links in illicit heroin samples (Figure 3).

### Introduction

The extent to which thin-layer chromatography (TLC) is used in forensic investigations varies considerably from laboratory to laboratory and is now very dependent on the alternative analytical techniques to be found within any particular laboratory. Invariably TLC is but one of a number of techniques that could be used for a particular analysis. On many occasions the alternatives are likely to be more precise and/or specific than TLC and, since these criteria are usually of paramount importance, are likely to be used preferentially. For example, the combination of radioimmunoassay, to carry out the rapid screening of samples for the presence of a member of a particular class of drug, and gas chromatography–mass spectrometry (GC–MS) for the identification or confirmation of the presence of a particular drug, is likely to provide a more precise and sensitive analysis than will the use of TLC.

The major advantages of TLC are its simplicity, low cost, and the selectivity of detection that may be obtained by the use of a wide range of location procedures, and these account for its use in many laboratories. Its major disadvantage can be its lack of sensitivity. This has been highlighted by the tendency of modern drugs to be more potent than in the past and consequently to be prescribed in much smaller doses. The amount of active material that is encountered during certain investigations is therefore often below the detection limits afforded by TLC, and in these cases another, more sensitive analytical methodology is obligatory.

### Illicit Drugs and Toxicological Studies

In forensic science, ‘drugs’ are encountered in two specific sets of circumstances, each of which requires quite different investigative procedures.

The first, the drugs investigation, is that in which the possession, illicit manufacture, and/or distribution of drugs of abuse, such as cannabis, heroin, amphetamine, and LSD, are involved. This type of

investigation is usually characterized by a large amount, in analytical terms, of material that is available for analysis; this is usually in the milligram range, but often kilograms of sample are accessible. The sample may consist of a powder and/or tablets found in the possession of an individual, it may originate from a much larger seizure of material, for example, a consignment being smuggled across international borders, or may be from a number of samples taken from the site of manufacture of the drug, i.e., an illicit laboratory.

For drugs analyses the major applications of TLC are concerned with the identification of cannabis and the screening of drug powders and tablets for their active constituents.

Two TLC systems are in use for cannabis investigations. The first consists of a silica gel plate sprayed with diethylamine immediately before use and a mobile phase of xylene–hexane–diethylamine (25:10:1 by vol). The second consists of a mobile phase of toluene in an open tank and a silica gel plate sprayed with a 10% solution of silver nitrate and dried before use. A general location reagent is Duquenois reagent (vanillin (2 g) and acetaldehyde (0.3 ml) in ethanol (100 ml)), which, after overspraying with hydrochloric acid, gives blue to violet colors with cannabinoids. A more specific reagent is Fast blue B solution (a freshly prepared 1% solution of Fast blue B salt (diazotized *o*-dianisidine)), with which cannabidiol gives an orange color, cannabinol a violet color, and  $\Delta^9$ -tetrahydrocannabinol a red color. The colors obtained with the Fast blue B reagent may be intensified by overspraying with sodium hydroxide or by exposing the plate to ammonia fumes.

The majority of the active ingredients of drug powders that are encountered in forensic examinations are basic in nature and may therefore be examined using one of the general systems described in the article on Toxicological Analysis. Visualization is carried out using a general reagent, such as acidified iodoplatinate solution (hydrochloric acid (5 ml) added to a solution of platinum(IV) chloride (0.25 g) and potassium iodide (5 g) made up to 100 ml), which, for example, gives violet colorations with amines. Since the number of individual drugs encountered in these types of investigation is relatively small, a better indication of the drug involved may be obtained by use of a more specific location reagent, such as Marquis reagent (a mixture of formaldehyde solution (1 ml) with sulfuric acid (9 ml)) for alkaloids related to morphine,

and/or running control substances on the same plate as the unknown sample.

A number of the tablets that are encountered during the examination of 'illicit' drugs contain the same active ingredients as the drug powders described above. Many, however, do not, and in these circumstances the scope of the investigation needs to be widened to include the large number of other substances that may be legitimately prescribed but which are nevertheless subject to abuse in some way. In this case a general screen for acidic and neutral drugs, as described in the article on TLC in analytical toxicology, would be carried out.

In the second set of circumstances – the toxicological investigation – 'drugs' are encountered after ingestion by an individual. These may include drugs of abuse, as well as those prescribed for medicinal use and a number of other miscellaneous poisons. Identification of a drug may be required to ascertain the cause of a suspicious death, to determine the cause of impairment of function, for example, in a driving case, or determining the involvement of drugs as a contributory factor in a crime such as murder or rape. The major differences between cases involving illicit drugs and toxicological investigations are concerned with the presentation of the sample, the amount of sample present, and the presence of other materials that may complicate the analysis. In drugs cases the compounds of interest may be separated relatively easily from the few other materials present, such as excipients. In toxicological cases the compounds of interest are invariably part of a complex biological matrix, such as urine, blood, or tissue, and often bound to proteins from which they must be released before analysis. In drugs cases the compound(s) of interest may usually be defined readily; toxicology cases may be complicated by the presence of the many naturally occurring compounds in the body and the presence of drug metabolites, which in some cases are found to the total exclusion of the parent drug. The amount of active material in a toxicology case, in contrast to the milligrams or kilograms available when illicit drugs are involved, is invariably at the nanogram per milliliter level or below. TLC may be used for samples, such as stomach contents and urine, that contain the greatest amount of drugs and their metabolites, but the levels found in blood are usually low and preclude the use of TLC. The methodology for this type of analysis is, again, covered in the article on TLC in analytical toxicology.

## Explosives Residues

Detection of many commercially available explosives found at the site of explosions may be achieved using

TLC with visualization using a modified Griess reagent. The ability of this method to provide a definitive identification has been questioned because of the false positives that may be observed from totally unrelated compounds. When TLC is employed for the examination of explosives residues it is therefore recommended that further confirmatory analyses should be carried out before the presence of explosives is reported.

Extraction of an explosive may be achieved using acetone or toluene in which nitroglycerin (NG), ethylene glycol dinitrate (EGDN), RDX, HMX, pentaerythritol tetranitrate (PETN), tetryl, and the nitrotoluenes are sufficiently soluble to allow detection at the levels that are usually encountered. A combination of mobile phases must be used for their separation by TLC because RDX and HMX are unresolved using ethyl acetate–petroleum ether, while chloroform–methanol will separate these two explosives but will not separate NG and PETN. Visualization is with a modified Griess reagent after hydrolysis with sodium hydroxide at 105°C. The Griess reagent used consists of sulfanilic acid (1 g) in 30% acetic acid (100 ml) mixed with glacial acetic acid (100 ml) added to the supernatant liquid obtained after dissolving  $\alpha$ -naphthylamine (1 g) in boiling water (230 ml) and allowing to cool. The reagent is highly sensitive to nitrates and to most nitro-containing organic explosives. Organic nitrites give pink to red colors; inorganic nitrites give red colors that immediately fade to yellow. If no color is obtained initially, the addition of zinc dust will bring about the rapid development of pink to red colors if inorganic nitrates or organic nitro compounds are present.

Confirmation of any positives is advisable by using techniques such as liquid chromatography (LC) in conjunction with MS or by infrared (IR) spectroscopy and GC in combination with MS.

## Gunshot Residues

A similar system to that used for explosives may be used for confirming the presence of, and identifying, smokeless powder flakes taken from hand swabs. In this case the Saltzman–Griess reagent is used as a test for nitrite ions released from NG and nitrocellulose (NC) by alkaline hydrolysis. NC exists in two forms, propellant grade and nonpropellant grade, the latter being used as a base for some lacquers, inks, resins, and films. These two forms differ in the lengths of their cellulose polymer chains and it is necessary to differentiate between them in order to confirm conclusively the presence of smokeless powder. This is accomplished by developing the TLC plate

consecutively with two mobile phases, methylcellosolve–95% ethanol (15:85 v/v) and toluene–petroleum ether–ethyl acetate (12:12:1 by vol). In the first system propellant-grade NC remains at the origin while nonpropellant NC and NG move with the solvent front. In the second system NG has an  $R_F$  of 0.3 while the NC remains stationary. A pink color is obtained from NC and NG with the visualization reagent that consists of 0.1% by weight of *N*-1-naphthylethylenediamine dihydrochloride in distilled water, 80 ml of which is used to dilute glacial acetic acid (14 ml). Sulfanilic acid (0.5 g) is then dissolved in the resulting solution, which is made up to 100 ml with water.

To overcome the problem of false positives it is now more usual, whenever possible, to use a scanning electron microscope to detect the metals, such as barium, associated with discharging of a firearm while the organic constituents of smokeless powder are preferably analyzed as for explosive residues above, i.e., by using LC followed by MS confirmation, GC–MS, etc.

## Inks

One of the major differences between forensic science and other areas of analytical chemistry is that in a large number of cases the determination of the absolute chemical composition of a material, for example, a fiber, an ink sample, or a paint flake, is not the major requirement. It is rather determining that two samples are, or are not, identical, i.e., are so similar that there is an incontrovertible link between a suspect and a crime or, alternatively, that they are so dissimilar that it can be shown incontrovertibly that there is no link between a suspect and a crime. For this to be accomplished successfully, therefore, any particular class of evidential material must possess a particular discriminating feature and there must be an appropriate analytical technique available to allow meaningful differences in this feature to be recorded.

TLC is used extensively for the study of inks in many types of case, particularly those involving forgery of cheques. The comparison and discrimination that may be obtained is in terms of both the visible dyestuffs and the ultraviolet (UV)-fluorescent components that are present. A number of methods are available for the comparison of the color of ink and these include microscopy, IR luminescence and reflectance, and also TLC. Ink colors can change rapidly when the writing is exposed to light and this tends to complicate the results obtained by microscopic examination, while

IR luminescence may be affected by the exposure of the ink to moisture and many common household chemicals.

Ballpoint ink samples may be removed from the written line using a blunt hypodermic needle or a scalpel and then dissolved in pyridine. A mobile phase of ethyl acetate–ethanol–water (70:35:30 by vol) has been used to separate the constituent dyes sufficiently to permit the discrimination of a number of examples, although on occasions it proves necessary to employ a second mobile phase, *n*-butanol–ethanol–water (50:10:15 by vol) to achieve sufficient discrimination.

This second mobile phase has been used for the examination of black ballpoint inks, with a densitometer being used to scan the TLC plate and locate the positions of the individual dyes after UV irradiation. The wavelength chosen, 580, 425, or 420 nm, was on the basis of the color of the ink and the dyes present. The resulting trace allows a more easy rigorous comparison of the results from different ink samples and allows any differences that there may be to be more easily discerned.

An examination of a number of blue and black fibertip pens and fluid pen inks, applied to both card and photographic papers, used a mobile phase similar to that used for the examination of ballpoint inks, namely *n*-butanol–ethanol–water (4:1:1 by vol), and showed a general agreement in the number, color, and  $R_F$  values of the dyes present in each ink despite there being a visual difference between samples of the same ink on paper and card. The effect of age of the ink sample was ably demonstrated when a similar investigation was carried out on 12-month-old dried ink samples, and four pairs of sample were erroneously concluded to be different. Good discrimination of inks from fibertip pens has also been reported using ethanol to extract the dyes from the ink and mobile phases of *n*-butanol–acetic acid–water (6:1:2 by vol) and *n*-butanol–acetic acid–water–dioxan (6:2:2:1 by vol) to effect separation of the components prior to both visual and UV examination of the plates.

The differences in analytical results obtained as inks age has been attributed to a decrease in the extraction efficiency of the solvent toward the constituents of the ink; the longer the ink has been on the paper the harder they are to extract. This has been attributed to a number of factors either in isolation or in combination. These include evaporation of the solvent from the ink, chemical reactions such as oxidation and polymerization of the constituents of the ink, and ink–paper interactions. The method used involves comparing the concentration of the components of the ink from a sample of unknown age with

those obtained from samples of known age. Because of the complicated factors involved, the method is only applicable if the ink used to provide the control results is of the same composition as the aged sample and has been used on the same type of paper. UV-visible spectrophotometry, TLC with densitometry, LC, and fluorescence were used to obtain the concentration measurements, but it was concluded that the TLC method was one of the more tractable since it did not reflect the solvent used for extraction. Extraction of the ink was effected with toluene or benzyl alcohol and the dyes were separated using a mobile phase of ethyl acetate-ethanol-water (70:35:30 by vol).

Although many investigations involve handwritten documents, a significant number are encountered that have been produced using typewriters. The comparison and discrimination of typewriter ribbons may be carried out in a similar way to that described for inks and a meaningful comparison may be made from a dye extracted from a single character. Pyridine is used to extract the ink from the ribbon. Using a combination of mobile phases of ethyl acetate-ethanol-water (70:35:30 by vol) and *n*-butanol-ethanol-water (50:10:15 by vol) it proved possible to distinguish all of the ribbons that were studied that were ostensibly of the same color but produced by different manufacturers. It was also possible to differentiate between different dye batches, and it was therefore concluded that if inks were indistinguishable using these two TLC systems, they originated either from the same ribbon or from one with the same ink formulation.

## Dyes

A major use of TLC in forensic science is the analysis of the dyes to be found in fibers.

There are a number of different types of fiber that may be encountered and equally there are a number of different classes of dye, although some of these may only be associated with particular types of fiber. The type of fiber and the class of dye both affect the detailed scheme employed for the extraction of the dye from the fiber and the subsequent chromatographic analysis of the extract. A detailed discussion of the extraction schemes employed is beyond the scope of this text but, for example, acid dyes are best extracted using a mixture of pyridine and water (4:3 v/v), while reactive dyes require extraction with 1,2-diaminoethane at 90°C for 1 h. Schemes have been developed for the extraction of: (1) acid-chrome dyes from wool; (2) direct and reactive dyes from cellulosic fibers; (3) azo dyes from

cotton viscose fibers; (4) acid and disperse dyes from polypropylene; and (5) disperse, acid, and basic dyes from polyamides, polyesters, and polyacrylonitriles.

The TLC systems then employed for the discrimination of fibers is dependent upon the type of dye involved and the practical approach will involve the use of as many, or as few, as are necessary to provide discrimination. The systems used are listed below.

### *Acid dyes*

- chloroform-water-methanol-880 ammonia (11:1:7:1 by vol);
- butan-2-ol-acetone-water-ammonia (4% v/v) (5:5:1:2 by vol);
- pyridine-amyl alcohol-ammonia (10% v/v) (4:3:3 by vol);
- butan-1-ol-glacial acetic acid-water (upper phase) (20:10:50 by vol);
- butan-1-ol-ethanol-water-glacial acetic acid (60:10:20:5 by vol);
- *n*-butyl acetate-pyridine-water (2:2:1 by vol); and
- butan-1-ol-880 ammonia-pyridine (4:1:3:2 by vol).

### *Basic dyes*

- butan-1-ol-glacial acetic acid-water (upper phase) (4:1:5 by vol);
- chloroform-propan-2-ol-pyridine-glacial acetic acid-water (6:8:3:1:1 by vol); and
- chloroform-glacial acetic acid-formic acid-water (8:6:6:1 by vol).

### *Direct dyes*

- butan-1-ol-ethanol-880 ammonia-pyridine-water (8:3:4:4:3 by vol);
- pyridine-butan-2-ol-880 ammonia (9:6:6 by vol); and
- pyridine-amyl alcohol-880 ammonia (4:3:3 by vol).

### *Disperse dyes*

- toluene-pyridine (8:2 v/v);
- hexane-methyl acetate-acetone (5:4:1 by vol); and
- toluene-methanol-acetone (20:2:1 by vol).

### *Reactive dyes*

- methanol-amyl alcohol-water (5:5:2 by vol) and
- propan-1-ol-methanol-water-880 ammonia (8:6:2:1 by vol).

An alternative parameter that has been used for the discrimination of fibers is an examination for the presence of optical brighteners that originate from the detergent regime to which the fibers have been exposed. These brighteners are mainly coumarin, benzazole, or stilbene derivatives and may be extracted, for all fibers except acrylics, using dimethyl-formamide in subdued light. In the case of acrylics, pyridine must be used for extraction. Four mobile phases have been used for separation of the individual brighteners: chloroform–isopropanol (100:1.5 v/v); acetone–5 mol l<sup>-1</sup> aqueous ammonia–n-heptane (45:5:10 by vol), methyl ethyl ketone–5 mol l<sup>-1</sup> aqueous ammonia–methanol (40:15:10 by vol), and pyridine–n-butanol–ethanol–880 ammonia (30:40:10:20 by vol). Their visualization is achieved using UV irradiation at 366 nm.

A TLC method for the analysis of the dyes extracted from car sidelights has been used to distinguish similarly colored lenses.

## Other Evidential Materials

Paint is encountered in a number of types of crime, particularly burglary where a door or window has been forced to gain entry and in a range of car-related crimes such as hit-and-run incidents. TLC has been shown to provide good discrimination between visually similar colored gloss paints on the basis of the organic pigments present. Red, orange, yellow, dark-blue, purple, and brown paints are best examined by making an extract of a paint flake with dichloromethane and using a TLC mobile phase of chlorobenzene–toluene–1,2-dichloromethane (1:1:1 by vol). This system is not as effective for green, blue–green, and light-blue paints, which are best studied by extraction using 1,2-dichlorobenzene and a TLC mobile phase of 1,2-dichlorobenzene–toluene–1,2-dichloroethane (2:1:1 by vol), which also improves the discrimination of dark-blue, purple, and brown paints.

The analysis of a pharmaceutical preparation can yield much useful information in addition to the identity of the active ingredient, the determination of which is usually a trivial analytical task. Illicit drug preparations seized in different locations are studied to determine whether they originate from the same source. Law-enforcement agencies may thus be provided, at any particular time, with an indication of the number of primary sources of a drug and are consequently able to utilize their resources more

effectively. Large sums of money are spent developing and testing drugs to ensure their safety before they reach the market, and this investment is protected by means of patents. Pharmaceuticals may therefore be synthesized and distributed with a high financial return by those who are not themselves prepared to go through this lengthy, and costly, procedure but who prefer to utilize procedures patented by others. Monitoring of patent infringements is an essential part of the analytical work of a pharmaceutical company. One parameter that may be used during both of these types of investigation is the characterization of the food dyes that are often used in tablets to give them a characteristic color. TLC forms an important part of the procedure used for their analysis. These dyes may be extracted using methanol or water, the stability and solubility of the dyes depending on the acidity of the extraction medium. The extract is screened using TLC with a mobile phase of trisodium citrate–water–ammonia (2 g:100 ml:5 ml) and this is often sufficient to be able to show the similarity of the extracts from different tablets. Should identification of the dyes be necessary this may be carried out using visible spectrophotometry at three different pH values, to give tentative identifications, followed by LC for a positive identification.

TLC may also be used for the comparison of cosmetic dyes; for example, those that occur in lipsticks, and of the rubber in tyres and for the analysis of bitumens.

## Volatile Substances

**R J Flanagan**, Guy's and St. Thomas' Hospital Trust, London, UK

### Introduction

Acute poisoning with volatile substances usually follows the deliberate inhalation of vapor in order to become intoxicated ['glue sniffing', inhalant abuse, solvent abuse, volatile substance abuse (VSA)]. Solvents from adhesives, notably toluene, some correcting fluids and thinners, hydrocarbons such as those found in cigarette lighter refills [usually liquefied petroleum gas (LPG)], aerosol propellants, and anesthetic gases such as nitrous oxide are amongst the compounds/products that may be abused in this way (Tables 1 and 2). Nail varnish/varnish remover (acetone and esters) and felt-tip marker pen fluids, although strong smelling, are probably too water soluble to be intoxicants. Methanol, ethanol, 2-propanol, and ethylene glycol, and also diesel fuel, aviation fuel (kerosene, Avgas), white spirit, turpentine (or substitute), and paraffin are not sufficiently volatile to be abused by inhalation. Petrol (gasoline), on the other hand, is often abused, especially in less well-off communities. Isobutyl and isopentyl ('amyl') nitrites are also inhaled in order to experience their vasodilator properties, sometimes by male homosexuals. In addition, those who ingest, or even more rarely inject, solvents or solvent-containing products, either accidentally or deliberately, and the victims of clinical, industrial, and domestic accidents may be poisoned by the compounds under consideration. Finally, chloroform, diethyl ether, and other volatiles are still used occasionally during crimes such as rape and murder, whilst a further volatile compound, chlorobutanol (1,1,1-trichloro-2-methyl-2-propanol), sometimes employed as a sedative and a preservative, has been used in doping racing greyhounds.

### Diagnosis of Acute Poisoning with Volatile Substances

VSA should be suspected in children and adolescents with 'drunken' behavior, unexplained listlessness, anorexia, and moodiness. The hair, breath, and clothing may smell of solvent, and empty adhesive tubes or other containers, potato crisp bags, cigarette lighter refills, or aerosol spray cans are often found.

The smell of solvent on the breath is related to the dose and duration of exposure and may last for many hours. The so-called 'glue-sniffer's rash' (perioral eczema) is probably caused by repeated contact with glue in a plastic or other bag held to the face. Although primarily a phenomenon of adolescence, it must be remembered that adults, especially those with ready occupational access to abusable volatiles, may also indulge in VSA. In the late 1970s, for example, it was estimated that some 1–1.6% of US dentists were abusing nitrous oxide.

The analytical toxicology laboratory may be asked to perform analyses for solvents and other volatile compounds in biological samples and related specimens to: (1) assist in the diagnosis of acute poisoning; (2) confirm a suspicion of chronic VSA in the face of denial from the patient and/or a caretaker; (3) aid the investigation of deaths where poisoning by volatile compounds is a possibility, including deaths associated with anesthesia; (4) aid investigation of rape or other assault, or other offences such as driving a motor vehicle or operating machinery, which may have been committed under the influence of volatile substances; (5) aid investigation of incidents such as rape or other assault in which volatile substances may have been administered to the victim; (6) help investigate fire or explosion where VSA might have been a contributory factor; and (7) assess occupational or environmental exposure to anesthetic or solvent vapor. However, other techniques such as ambient air monitoring or, in a few instances, the measurement of urinary metabolite excretion may be more appropriate in this latter context.

The analysis of volatiles presents particular problems. First, many of the compounds of interest occur commonly in laboratories and this necessitates special precautions against contamination and interference. Second, collection, storage, and transport of biological samples must be controlled as far as practicable in order to minimize loss of analyte – quantitative work is futile if very volatile compounds such as propane are encountered unless special precautions are taken to prevent the loss of analyte from the sample prior to the analysis. Third, many compounds of interest are excreted unchanged via the lungs and thus blood (and/or other tissues in fatalities), and not urine, is usually the sample of choice. Finally, the interpretation of results can be difficult, especially if legitimate exposure to solvent vapor is a possibility.

A diagnosis of VSA should be based on a combination of circumstantial, clinical, and analytical

**Table 1** Some volatile substances that may be abused by inhalation

Hydrocarbons	Oxygenated compounds and others
Aliphatic	Acetylene Butane <sup>a</sup> Isobutane (2-methylpropane) <sup>a</sup> Hexane <sup>b</sup> Propane <sup>a</sup>

Sevoflurane [fluoromethyl 2,2,2-trifluoro-1-(trifluoromethyl)ethyl ether]
Xenon

<sup>a</sup>Principal components of purified LPG; some unpurified LPGs can contain up to 40% (v/v) unsaturated compounds (butenes and propenes).

<sup>b</sup>Commercial 'hexane' mixture of hexane and heptane with small amounts of higher aliphatic hydrocarbons.

<sup>c</sup>Mainly *m*-xylene (1,3-dimethylbenzene).

<sup>d</sup>Mixture of aliphatic and aromatic hydrocarbons with boiling range 40–200°C.

<sup>e</sup>Mixtures of pentanes, hexanes, etc., with specified boiling ranges (e.g., 40–60°C).

<sup>f</sup>Abused primarily for its vasodilator properties.

<sup>g</sup>Commercial 'amyl nitrite', mainly isopentyl nitrite but other nitrites also present.

evidence rather than on any one factor alone. It is especially important to consider all circumstantial evidence in cases of possible VSA-related sudden death since suicide or even homicide cannot be excluded simply on the basis of the toxicological examination. There have been a number of reports of the use of inhalational anesthetics for suicidal purposes and there has been one example in the UK of a serial murderer whose victims were thought initially to have died as a result of VSA.

## Analytical Methods

The analysis of biological samples for solvents and other volatiles that may be abused by inhalation has similarities to the analysis of methanol, ethanol, and 2-propanol. However, poisoning with these latter compounds is normally the result of ingestion or occupational exposure to vapor. Headspace gas chromatography (GC) with flame ionization and/or electron capture detection (FID and/or ECD) is widely used in the analysis of volatiles in blood and other biological specimens that may be obtained without using special apparatus such as breath-collection tubes. Nitrous oxide and most halogenated compounds respond on the ECD, although the thermal conductivity detector (TCD) may be used as an alternative if nitrous oxide poisoning is suspected. Although not reported as yet, abuse of xenon is a possibility. GC methods for this element would require a TCD or mass spectrometry (MS). Direct MS of expired air can also detect many compounds several days postexposure. However, at present the use of this technique is limited by the need to take breath directly from the patient. Vapor-phase infrared (IR) spectrophotometry may be useful in the analysis of abused products or ambient atmospheres.

**Table 2** Some products that may be abused by inhalation<sup>a</sup>

<i>Product</i>	<i>Major volatile components</i>
Adhesives	
Balsa wood cement	Ethyl acetate
Contact adhesives	Butanone, hexane, toluene, and esters
Cycle tyre repair cement	Toluene and xylenes
Poly(vinyl chloride) cement	Acetone, butanone, cyclohexanone, trichloroethylene
Woodworking adhesives	Xylenes
Aerosols	
Air freshener	LPG, DME, and/or fluorocarbons <sup>b</sup>
Deodorants, antiperspirants	LPG, DME, and/or fluorocarbons <sup>b</sup>
Fly spray	LPG, DME, and/or fluorocarbons <sup>b</sup>
Hair lacquer	LPG, DME, and/or fluorocarbons <sup>b</sup>
Paint	LPG, DME, and/or fluorocarbons <sup>b</sup> and esters
Anesthetics/analgesics	
Inhalational	Nitrous oxide, cyclopropane, diethyl ether, halothane, enflurane, desflurane, isoflurane, methoxyflurane, sevoflurane, xenon
Topical	Ethyl chloride, fluorocarbons <sup>b</sup>
Dust removers ('air brushes')	DME, fluorocarbons <sup>b</sup>
Commercial dry cleaning and degreasing agents	Dichloromethane, FC 113, FC 141b, methanol, 1,1,1-trichloroethane, tetrachloroethylene, toluene, trichloroethylene (now very rarely carbon tetrachloride, 1,2-dichloropropane)
Domestic spot removers and dry cleaners	Dichloromethane, 1,1,1-trichloroethane, tetrachloroethylene, trichloroethylene
Fuel gases	
Cigarette lighter refills	LPG
'Butane'	LPG
'Propane'	Propane and butanes
Halocarbon fire extinguishers	BCF, FC 11, FC 12
Paints/paint thinners	Acetone, butanone, esters, hexane, toluene, trichloroethylene, xylenes
Paint stripper	Dichloromethane, methanol, toluene
Racing fuel super-charge	Nitrous oxide
'Room odorizer'	Cyclohexyl nitrite, isobutyl nitrite
Surgical plaster/chewing gum remover	1,1,1-Trichloroethane, trichloroethylene
Typewriter correction fluids/thinners (some)	1,1,1-Trichloroethane
Whipped cream dispensers	Nitrous oxide

<sup>a</sup> see **Table 1** for full chemical names of some compounds; the composition of some products varies with time and country of origin.

<sup>b</sup> Nowadays often 1,1,1,2-tetrafluoroethane (FC 134a), but chlorodifluoromethane (FC 22), 1,1-difluoroethane (FC 152a), difluoromethane (FC 32), pentafluoroethane (FC 125), perfluoropropane (FC 218), and 1,1,1-trifluoroethane (FC 143a) might also be encountered.

If the analyte is very volatile (e.g., propane or butane) and a quantitative analysis is required, a blood sample should be collected directly into the headspace vial in which the analysis will be carried out. Many other volatile compounds are relatively stable in blood and other tissues if simple precautions are taken. In the case of blood, the container used for the sample should be glass, preferably with a cap lined with metal foil; greater losses may occur if plastic containers are used. The tube should be as full as possible and should only be opened when required for analysis and then only when cold (4°C). If the sample volume is limited, it is advisable to select the container to match the volume of blood so that there is minimal headspace. An anticoagulant [sodium ethylenediaminetetraacetate (EDTA) or lithium heparin] should be used. Specimen storage between -5 and 4°C is recommended and 1% (w/v)

sodium fluoride should be added to minimize esterase and other enzymic activity. Tissues (~10 g each of brain, lung, liver, kidney, and subcutaneous fat) should also be obtained if a necropsy is to be performed in addition to standard toxicological specimens if available (femoral blood, urine, stomach contents, vitreous humor). Tissues should be stored before analysis in the same way as blood. No preservative should be added. Products thought to have been abused or otherwise implicated in the incident (and stomach contents if ingestion is suspected) should be packed, transported, and stored entirely separately from (other) biological specimens to avoid cross-contamination. Investigation of deaths occurring during or shortly after anesthesia should include the analysis of the inhalation anesthetic(s) used in order to exclude an administration error.

## Headspace Gas Chromatography

Packed columns, for example, 2 m  $\times$  2 mm i.d. 0.3% (w/w) Carbowax 20M on Carbowax C programmed from 35°C to 175°C, have been used extensively in conjunction with headspace sample preparation for the GC analysis of volatile compounds in biological specimens. On-column septum injections of up to 400  $\mu$ l headspace can be performed and good sensitivity (of the order of 0.1 mg l<sup>-1</sup> or better using 200  $\mu$ l of sample) can be obtained. Disadvantages include the poor resolution of some very volatile substances, a long total analysis time, and variation in the peakshape given by alcohols between different batches of column packing. Porous layer open tubular (PLOT) columns give good retention and thus resolution of compounds with similar relative formula mass, but peakshapes of polar compounds are poor and it is difficult to screen for compounds of widely different volatility in one analysis.

Bonded-phase wide-bore capillary columns permit relatively large-volume septum injections and can offer advantages of improved efficiency, reproducibility, and reliability. A 60 m  $\times$  0.53 mm i.d. fused silica capillary coated with the dimethylpolysiloxane SPB-1 (5  $\mu$ m film thickness) programmed from 40°C to 200°C offers many advantages over packed column and PLOT systems. Improved resolution of very volatile compounds is obtained and, even with an initial temperature of 40°C, the total analysis time can be reduced to 26 min, and good peakshapes can be obtained even for alcohols (Figure 1). Moreover, splitless septum injections of up to 300  $\mu$ l headspace can be performed with no noticeable effect on column efficiency; hence, sensitivity is at least as good as that attainable with a packed column. Indeed, nowadays packed and PLOT columns are only used in specific applications or if a capillary GC is not available.

The use of a capillary column together with two different detectors (FID and ECD) confers a high degree of selectivity, particularly for low formula mass compounds where there are very few alternative structures. If more rigorous identification is required, GC combined with MS or Fourier transform IR (FTIR) spectrometry may be used. However, GC-MS cannot be efficient when the fragments produced are less than  $m/z$  40, particularly if the instrument is used for other purposes as well as solvent analyses. In particular, the available sensitivity and spectra of the low molecular weight alkanes renders them very difficult to confirm by GC-MS. Inertial spray MS allows introduction of biological fluids directly into the MS without prior chromatographic

analysis and has been used in the analysis of halothane in blood during anesthesia.

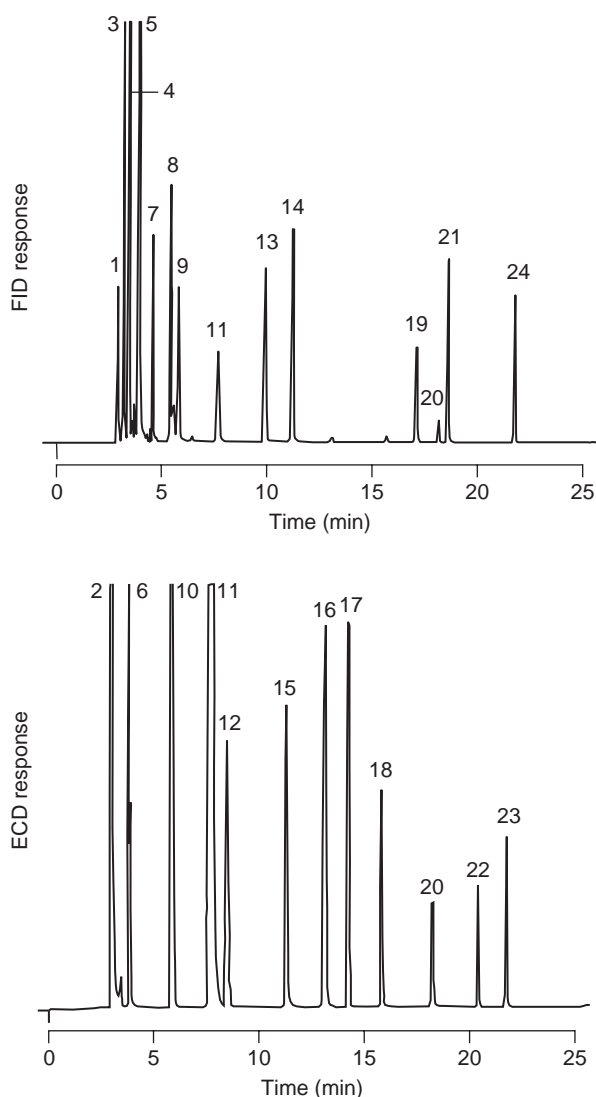

GC-FTIR is generally more appropriate than GC-MS in the analysis of volatiles, but sensitivity is poor particularly when compared with ECD. In addition, interference, particularly from water and carbon dioxide in the case of biological specimens, can be troublesome. 'Purge and trap' and multiple headspace extraction offer ways of increasing sensitivity and, although not needed for most clinical and forensic applications, have been used either in conjunction with GC-FTIR or in occupational/environmental monitoring. Pulse heating has also been employed in the analysis of volatiles in biological specimens. Advantages of this latter technique include the use of a small sample volume (0.5–5  $\mu$ l), short extraction time, and lack of matrix effects.

**Use of the SPB-1 column system** A qualitative standard mixture is first analyzed (see Figure 1). A reagent 'blank' analysis is then performed to monitor interference from the laboratory atmosphere. A sealed headspace vial containing internal standard solution (1,1,2-trichloroethane + ethylbenzene in analyte-free diluted whole blood) is incubated (65°C, 15 min) and a portion (100–300  $\mu$ l) of the headspace is taken for analysis using a warmed (40°C) gas-tight glass syringe. Subsequently, the sample (whole blood, plasma, serum, or urine) (200  $\mu$ l) is added to the same vial and, after reincubation (65°C, 15 min), a further portion of headspace is taken for analysis.

Tissue samples can be analyzed after incubation with a proteolytic enzyme (subtilisin A) in a sealed headspace vial. The 'blank' analysis should be performed in a separate vial. Adhesives and similar products should be introduced into a glass vial. The vial is sealed and, after 1–15 min, a portion (50–100  $\mu$ l) of the headspace is analyzed. Liquids can be analyzed in the same way, except that it is often possible to withdraw a portion (5–50  $\mu$ l) of the headspace directly from the container. Aerosols and fuel gases can be analyzed after releasing a portion of the product into a headspace vial and sealing the vial.

Quantitative analyses can be performed either isothermally or with a temperature program. For analytes that are liquids at room temperature, assay calibration is by analysis of standard solutions prepared in analyte-free human blood. The same calibration solutions are used in the analysis of tissue digests. Analyte concentrations in the range 0.1–10 or 0.5–50 mg l<sup>-1</sup> are usually adequate in acute poisoning. Portions of the standards are transferred to headspace vials for analysis as described above, and a

**Figure 1** Analysis of a standard volatile mixture. Column: 80 m  $\times$  0.53 mm i.d. SPB-1 (5  $\mu$ m film). Carrier gas: helium (flow rate 8.6 ml min<sup>-1</sup>). Oven temperature: 40°C (6 min), then to 80°C at 5°C min<sup>-1</sup>, then to 200°C at 10°C min<sup>-1</sup> (run time 26 min). Injection: 10  $\mu$ l vapor. Detector sensitivities (fsd): FID, 3.2 nA; ECD, 64 kHz. Peaks: 1, propane; 2, FC 12; 3, dimethyl ether; 4, isobutane; 5, butane; 6, BCF; 7, ethanol; 8, acetone; 9, 2-propanol; 10, FC 11; 11, FC 113; 12, halothane; 13, butanone; 14, hexane; 15, chloroform; 16, 1,1,1-trichloroethane; 17, carbon tetrachloride; 18, trichloroethylene; 19, methyl isobutyl ketone; 20, 1,1,2-trichloroethane (internal standard); 21, toluene; 22, tetrachloroethylene; 23, 2,2,2-trichloroethanol; 24, ethyl benzene (internal standard). (Reproduced with permission from Streete PJ, Ruprah M, Ramsey JD, and Flanagan RJ (1992) Detection and identification of volatile substances by head-space capillary gas chromatography to aid the diagnosis of acute poisoning. *Analyst* 117: 1111–1127. The Royal Society of Chemistry.)

calibration graph of peak height ratio of analyte to internal standard against analyte concentration is prepared. Often, either 1,1,2-trichloroethane or ethylbenzene can be used as the internal standard.

For analytes that are gases at room temperature, assay calibration is much more complicated and involves preparation of dilutions of gaseous calibration mixtures.

Compounds that do not elute during the program generally have boiling points of 170°C or above and Kovats retention indices on SE-30/OV-1/OV-101 packed columns of 1000 or more. ECD-responding compounds are primarily halogenated substances, but many compounds containing nitro- or keto-moieties also respond. Other substances such as allyl isothiocyanate and nitrous oxide show a good response. In contrast, the ECD response to compounds such as 1,1,1,2-tetrafluoroethane is relatively poor and some ketones, for example, the heptanones, show no response.

The retention data are highly reproducible in routine use and should be applicable to other dimethylpolysiloxane-coated capillaries (OV-1, SE-30, etc.) of similar dimensions and film thickness. Retention times are more convenient than retention indices when identifying unknowns. The analysis of a blood specimen from an adolescent who died after abusing 'butane' gas and vapor from a typewriter correcting fluid is shown in **Figure 2**. The analysis of blood from a patient who died after inhaling vapor from an electrical component cleaner is illustrated in **Figure 3**. Note that the concentrations of the components of interest were well above the limit of detection of the system. Indeed, although no formal studies have been performed, the limit attainable appears to be of the order of 0.01 mg l<sup>-1</sup> for ECD-responding compounds and 0.1 mg l<sup>-1</sup> for the remainder.

## Pharmacokinetics and the Interpretation of Results

Knowledge of the pharmacokinetics of volatile compounds is important in understanding the rate of onset, the intensity, and the duration of intoxication with these substances. The UK Maximum Exposure Limit (MEL) or Occupational Exposure Standard (OES) (**Table 3**) provide information on the relative toxicities of different compounds after chronic exposure to relatively low concentrations of vapor.

Inhaled compounds may rapidly attain high concentrations in well-perfused organs (brain, heart), while concentrations in muscle and adipose tissue may be very low. Should death occur, this situation is 'frozen' to an extent, but if exposure continues the compound will accumulate in less accessible (poorly perfused) tissues, only to be slowly released once exposure ceases. Thus, the plasma concentrations of

**Figure 2** Analysis of a whole blood specimen (200  $\mu$ l) from a patient who died after abusing a cigarette lighter refill and a typewriter correcting fluid containing 1,1,1-trichloroethane. GC conditions as for **Figure 1**. Injection: 300  $\mu$ l headspace. Detector sensitivities (fsd): FID 80 pA, ECD 2 kHz. Whole blood 1,1,1-trichloroethane concentration 1.2 mg l<sup>-1</sup>. (Reproduced with permission from Streete PJ, Ruprah M, Ramsey JD, and Flanagan RJ (1992) Detection and identification of volatile substances by head-space capillary gas chromatography to aid the diagnosis of acute poisoning. *Analyst* 117: 1111–1127. The Royal Society of Chemistry.)

some compounds may fall monoexponentially, while others may exhibit two (or more) separate rates of decline (half-lives).

The solubility of a volatile compound in blood is an important influence on the rate of absorption, tissue distribution, and elimination of the compound. The partition coefficients of a number of compounds between air, blood, and various tissues have been measured *in vitro* using animal tissues, and some *in vivo* distribution data have been obtained from postmortem tissue measurements in humans (**Table 3**). However, these latter data must be used with caution

**Figure 3** Analysis of a whole blood specimen (200  $\mu$ l) from a patient who died after abusing an aerosol designed for cleaning electrical components that contained FCs 11, 12, and 113. GC conditions as for **Figure 1**. Injection: 150  $\mu$ l headspace. Detector sensitivities (fsd): FID 160 pA, ECD 4 kHz. Whole blood FC 11 and FC 113 concentrations 3.2 and 1.0 mg l<sup>-1</sup>, respectively. (Reproduced with permission from Streete PJ, Ruprah M, Ramsey JD, and Flanagan RJ (1992) Detection and identification of volatile substances by head-space capillary gas chromatography to aid the diagnosis of acute poisoning. *Analyst* 117: 1111–1127. The Royal Society of Chemistry.)

since there are many difficulties inherent in such measurements (sampling variations, analyte stability, external calibration, etc.). Published data on the elimination half-lives of volatile substances (**Table 3**) are not easily comparable, either because too few samples were taken or the analytical methods used did not have sufficient sensitivity to measure the final half-life accurately.

### Metabolism of Volatile Substances

Exogenous compounds may be metabolized in a number of ways, a frequent result being the production of metabolites of greater polarity (water solubility) and thus lower volatility than the parent compound. The pharmacological activity and

**Table 3** Physical properties and pharmacokinetic data of some volatile compounds

<sup>a</sup>UK MEL/OES (8 h time weighted average) (Health and Safety Executive. EH40/2002. *Occupational Exposure Limits 2002*. Norwich, HMSO).<sup>b</sup>Figures in parentheses indicate compound gas at 20°C.<sup>c</sup>Terminal phase plasma half-life.<sup>d</sup>Longer after high doses.<sup>e</sup>As components of LPG.<sup>f</sup>Experimental: 37°C.

Data summarized from Baselt (2002), Fiserova-Bergerova (1983) and Pihlainen and Ojanperä (1998).

pharmacokinetics of any metabolite(s) often differ from those of the parent compound(s). After ingestion, extensive hepatic metabolism can reduce systemic availability ('first-pass' metabolism). Many volatile substances, including butane, dimethyl ether, most fluorocarbon refrigerants/aerosol propellants, isobutane, nitrous oxide, propane, tetrachloroethylene, and 1,1,1-trichloroethane, are largely eliminated unchanged in exhaled air. Others are partly eliminated in exhaled air and also metabolized in the liver and elsewhere, the metabolites being eliminated in exhaled air or in urine (Table 4), or incorporated into intermediary metabolism.

### Interpretation of Qualitative Results

The likelihood of detecting exposure to volatile substances by headspace GC of blood is influenced by the dose and duration of exposure, the time of sampling in relation to the time elapsed since exposure, and the precautions taken in the collection and storage of the specimen. In a suspected VSA- or anesthetic-related fatality, analysis of tissues (especially fatty tissues such as brain) may prove useful since high concentrations of volatile compounds may be present even if very little is detectable in blood.

Analysis for metabolites in urine may extend the time in which exposure may be detected but, of the compounds commonly abused, only toluene, the xylenes, and some chlorinated solvents, notably trichloroethylene, have suitable metabolites (see Table 4). Chronic petrol sniffing has been diagnosed by the measurement of blood lead concentrations, although with the move to lead-free petrol in many countries this is likely to be less useful in future. Petrol sniffing has also been diagnosed by detection of aromatic components such as toluene and ethylbenzene in blood. One consequence of the move to lead-free petrol has been that the aromatic content (including benzene content) of some kinds of petrol has increased – ironically benzene might present a greater danger in 'sniffers' than did lead. Abuse of the fluorinated anesthetic methoxyflurane has been detected by measuring serum and urine fluoride ion concentrations. With some kinds of petrol and other complex mixtures such as petroleum ethers (Table 1), however, the blood concentrations of the individual components are often below the limit of detection of headspace GC methods even after significant inhalational exposure.

Detection of a volatile compound in blood does not always indicate VSA or occupational/environmental exposure to solvent vapor. Acetone and some of its homologs may occur in high concentrations in ketotic patients. Large amounts of acetone and

butanone may also occur in blood and urine from children with acetoacetylcoenzyme A thiolase deficiency, for example, and may indicate the diagnosis. In addition, acetone is the major metabolite of 2-propanol in humans (Table 4). Conversely, 2-propanol has been found in blood from ketotic patients. Other ketones may also give rise to alcohols *in vivo*. Cyclohexanol, for example, is the principal metabolite of cyclohexanone in man (Table 4). Other volatile compounds such as halothane or chlorobutanol may be used in therapy or inadvertently added to the sample as a preservative. When interpreting the results of qualitative analyses it is important to remember that some compounds often occur in association – one with another (Table 5).

The use of aerosol disinfectant preparations when collecting specimens may contaminate the sample if an aerosol propellant is used. Contamination of blood samples with ethanol or 2-propanol may also occur if an alcohol-soaked swab is used to cleanse skin prior to venepuncture. Gross contamination with technical xylene (a mixture of *o*-, *m*-, and *p*-xylene together with ethylbenzene) has been found in blood collected into Sarstedt Monovette Serum Gel blood collection tubes; contamination with toluene (up to  $22 \text{ mg l}^{-1}$ ), 1-butanol, ethylbenzene, and xylene has been found in batches of these same tubes. Contamination with 1-butanol or 2-methyl-2-propanol occurs commonly in blood collected into tubes coated with EDTA. Care should be taken when handling frozen tissue prior to analysis as any compounds present in ambient air may condense on the cold surface and give rise to false positives. Processing blank frozen tissue can control for this possibility.

The interpretation of case data involving chloroform is particularly difficult, especially since this compound is still sometimes used in the course of crimes such as rape and murder. In addition to sometimes being present in drinking water at low concentrations, chloroform is found in a variety of medicinal preparations, in cigarette smoke, soft drinks, margarines, and in swimming pools if a chlorination plant is in operation. A further possible source of chloroform on headspace GC is from thermal decomposition of trichloroacetic acid. Trichloroacetic acid is a metabolite of several compounds including the solvent trichloroethylene (Table 5) and the drugs chloral hydrate, dichloralphenazone, and triclofos. Trichloroacetic acid has a half-life in blood of 3–5 days and thus may be detected for a relatively long time after exposure to, or ingestion of, a precursor. Trichloroacetic acid plasma concentrations of up to  $40 \text{ mg l}^{-1}$  have been reported after occupational exposure to trichloroethylene vapor.

**Table 4** Metabolites of some solvents and other volatile substances that may be measured to assess exposure<sup>a</sup>

<i>Compound</i>	<i>FW<sub>t</sub></i>	<i>Parent compound</i>	<i>Fluid</i>	<i>Normal<sup>b</sup></i>	<i>High<sup>c</sup></i>	<i>Comment</i>
Acetaldehyde	44.1	Ethanol	Blood	0.2 mg l <sup>-1</sup>	Not known	Blood/urine acetone concentrations can rise to 2 g l <sup>-1</sup> in ketosis. 2-Propanol also acetone metabolite
Acetone	58.1	2-Propanol	Blood	10 mg l <sup>-1</sup>	–	
			Urine	10 mg l <sup>-1</sup>	80 mg l <sup>-1</sup>	
4-Aminophenol	109.1	Aniline	Urine	–	10 mg l <sup>-1</sup>	The bromide concentrations associated with toxicity are lower after exposure to organobromines than when bromide salts given orally
Bromide ion	79.9	Bromomethane, other organobromines	Serum	10 mg l <sup>-1</sup>	40 mg l <sup>-1</sup>	
Butoxyacetate	132.2	2-Butoxyethanol	Urine	–	100 mg l <sup>-1</sup>	CO blood half-life 13 h breathing air, atmospheric pressure (CO half-life 5 h after inhalation of CO). Blood HbCO useful indicator of chronic exposure
Carbon monoxide	28.0	Dichloromethane	Blood	<5% HbCO	>20% HbCO	
Cyanide ion	26.0	Acetonitrile, acrylonitrile, other organonitriles	Blood	0.2 mg l <sup>-1</sup> (nonsmokers)	2 mg l <sup>-1</sup>	Cyanide metabolized to thiocyanate; both compounds may accumulate during chronic exposure
Cyclohexanol	100.2	Cyclohexane, cyclohexanone	Urine	–	5 mg l <sup>-1</sup>	Additional cyclohexane metabolites: <i>trans</i> -1,2-cyclohexanediol, <i>trans</i> -1,4-cyclohexanediol (alcohol metabolites excreted mainly as glucuronides in adults)
Cyclohexanone	98.2	Cyclohexane, cyclohexanol	Urine	–	0.5 mg l <sup>-1</sup>	See entry for cyclohexanol above
2,5-Dichlorophenol	163.0	1,4-Dichlorobenzene	Urine	–	100 mg l <sup>-1</sup>	
Dimethylsulfone	94.1	Dimethylsulfoxide	Urine	–	Not known	0.8 g l <sup>-1</sup> legal UK driving limit
Ethanol	46.1	Ethyl acetate	Blood	0.1 g l <sup>-1</sup>	0.8 g l <sup>-1</sup>	
Ethoxyacetate	104.1	Ethoxyethanol, 2-ethoxyethyl acetate	Urine	–	50 mg l <sup>-1</sup>	
β-Hydroxyethoxyacetate	120.1	1,4-Dioxane	Urine	–	0.5 g l <sup>-1</sup>	Dioxane-2-one also found in urine
Fluoride	19.0	Methoxyflurane and some other organofluorines	Serum	0.2 mg l <sup>-1</sup>	2 mg l <sup>-1</sup>	
			Urine	1 mg l <sup>-1</sup>	2 mg l <sup>-1</sup>	
Formate	46.0	Formaldehyde, methanol, methyl formate	Urine	20 mg l <sup>-1</sup>	30 mg l <sup>-1</sup>	
2,5-Hexanedione + 4,5-dihydroxy-2-hexanone	–	Hexane, 2-hexanone (MBK)	Urine	–	5 mg l <sup>-1</sup>	2-Hexanol and 2-hexanone additional hexane metabolites
Hippurate	179.2	Toluene	Urine	0.2 g l <sup>-1</sup>	2 g l <sup>-1</sup>	Not ideal indicator of toluene exposure as there are other (dietary, pharmaceuticals) sources of benzyl alcohol/benzoate hence hippurate
Mandelate	152.1	Ethylbenzene, styrene	Urine	0.005 g l <sup>-1</sup>	2 g l <sup>-1</sup>	Phenylglyoxylic acid also urinary metabolite
Methanol	32.0	Methyl acetate, methyl formate	Urine	–	30 mg l <sup>-1</sup>	
N-Methylacetamide	73.1	N,N-Dimethylacetamide	Urine	–	65 mg l <sup>-1</sup>	

<i>N</i> -Methylformamide	59.1	<i>N,N</i> -Dimethylformamide	Urine	–	15 mg l <sup>-1</sup>	Hydroxymethylformamide and formamide additional metabolites
4-Methyl-2-pentanone	100.2	Methyl isobutyl ketone	Urine	–	3.5 mg l <sup>-1</sup>	Hippurate and other methylphenols additional toluene metabolites
2-Methylphenol ( <i>o</i> -cresol)	108.1	Toluene	Urine	–	3 mg l <sup>-1</sup>	
<i>Trans,trans</i> -Muconate ( <i>t,t</i> -MA)	142.1	Benzene	Urine	–	2 mg l <sup>-1</sup>	Phenol and <i>S</i> -phenylmercapturic acid additional benzene metabolites
Nitrite ion	46.0	Butyl nitrite, isopentyl nitrite, other organonitrites	Plasma	2.5 mg l <sup>-1</sup>	Not known	Glycolate and glyoxylate also plasma and urinary ethylene glycol metabolites
			Urine	–	10 mg l <sup>-1</sup>	
Oxalate	90.0	Ethylene glycol	Urine	2.5 mg l <sup>-1</sup>	4 mg l <sup>-1</sup>	
Phenol	94.1	Benzene	Urine	0.1 mg l <sup>-1</sup>	50 mg l <sup>-1</sup>	Excreted as sulfate and glucuronide conjugates. Other metabolites include catechol and hydroquinone. Urinary phenol excretion not a reliable indicator of benzene exposure. <i>trans,trans</i> -MA and <i>S</i> -phenyl mercapturic acid excretion have been used to assess exposure
<i>S</i> -Phenyl-mercapturate	239.2	Benzene	Urine	–	45 µg l <sup>-1</sup>	<i>trans, trans</i> -MA and phenol additional benzene metabolites
2-Propanol	60.1	Acetone	Blood	–	2.5 g l <sup>-1</sup>	Acetone also 2-propanol metabolite
Thiocyanate ion	58.1	Acetonitrile, acrylonitrile, other organonitriles	Plasma	4 mg l <sup>-1</sup> (non smokers) 20 mg l <sup>-1</sup> (heavy smokers)	120 mg l <sup>-1</sup>	Cyanide/thiocyanate may accumulate during chronic exposure.
2-Thiothiazolidine-4-carboxylate (TTCA)	163.2	Carbon disulfide	Urine	–	8 mg l <sup>-1</sup>	TTCA glutathione conjugate of carbon disulfide. Urinary TTCA excretion reliable indicator of exposure
Tolurates (methylhippurates)	193.2	Xylenes	Urine	0.01 mg l <sup>-1</sup>	1.5 g l <sup>-1</sup>	Metabolite of 2,2,2-trichloroethanol Also metabolite of chloral hydrate, dichloralphenazone, and triclofos
Trifluoroacetate	114.0	Halothane and some other fluorinated anesthetics	Urine	–	2.5 mg l <sup>-1</sup>	
Trichloroacetate	163.4	Trichloroethylene	Urine	–	100 mg l <sup>-1</sup>	
2,2,2-Trichloroethanol	149.4	Trichloroethylene	Plasma	10 mg l <sup>-1</sup>	50 mg l <sup>-1</sup>	

<sup>a</sup>Urinary excretion often expressed as a ratio to creatinine.

<sup>b</sup>Upper limit of normally expected or 'nontoxic' concentration.

<sup>c</sup>Lower limit of concentration associated with toxicity/occupational exposure action limit.

**Table 5** Associated volatile compounds<sup>b</sup>

Compound	Associated compound(s)
Acetone	Butanone and higher ketones in ketoacidosis, 2-propanol (metabolite <sup>a</sup> )
BCF	FC 11
Butane	Butanone (metabolite <sup>a</sup> ), isobutane, 2-butanol (metabolite <sup>a</sup> ), propane
Cyclohexanone	Cyclohexanol (metabolite)
Dimethyl ether	FC 22 or other fluorocarbon
Ethanol	Propanols and higher alcohols if bacterial fermentation has occurred; methanol or other volatile poisons if denatured/synthetic alcohol has been consumed
Ethyl acetate <sup>a</sup>	Ethanol (metabolite)
Ethylbenzene	See xylenes below
FC 11	BCF, FC 12
FC 12	FC 11
FC 22	Dimethyl ether
Halothane	2-Chloro-1,1-difluoroethylene, 2-chloro-1,1,1-trifluoroethane (metabolites <sup>a</sup> )
Isobutane	Butane, 2-methyl-2-propanol (metabolite <sup>a</sup> ), propane
Isobutyl nitrite <sup>a</sup>	2-Methyl-1-propanol (degradation product)
Isopentyl nitrite <sup>a</sup>	3-Methyl-1-butanol (degradation product)
Methyl acetate <sup>a</sup>	Methanol (metabolite)
Propane	Butane, isobutane, 2-propanol (metabolite <sup>a</sup> )
2-Propanol	Acetone (metabolite)
2,2,2-Trichloroethanol	Trichloroethylene (also metabolite of chloral hydrate, dichloralphenazone, and triclofos)
Trichloroethylene	2,2,2-Trichloroethanol (metabolite), chloroform [possibly from thermal degradation of trichloroacetic acid (metabolite) <i>in vitro</i> ]
Xylenes	<i>ortho</i> -, <i>meta</i> -, and <i>para</i> -Xylene occur together in technical xylene, <i>m</i> -xylene predominating. Ethylbenzene also contaminant in technical xylene

<sup>a</sup> Rarely found.<sup>b</sup> See **Table 1** for full chemical names of certain compounds.

In 25 Caucasian adult women in Florida, USA, over a period of 6 months average plasma chloroform concentrations were generally less than  $25 \mu\text{g l}^{-1}$ , but in two subjects plasma chloroform concentrations of  $2.9 \text{ mg l}^{-1}$  and  $4.0 \text{ mg l}^{-1}$ , respectively, were found during routine sampling. All subjects were carefully screened to exclude occupational and recreational exposure to chloroform and other compounds that could give rise to chloroform on headspace GC. At the other extreme, postmortem blood chloroform concentrations in fatalities involving this agent have been reported as  $10\text{--}50 \text{ mg l}^{-1}$ .

It is well known that ethanol may be both produced and metabolized by microbial action in biological specimens. Small amounts of hexanal may arise from degradation of fatty acids in blood on long-term storage even at  $-5$  to  $-20^\circ\text{C}$ . Hexanal is resolved from toluene on the SPB-1 capillary GC system discussed above, but resolution may be lost if an isothermal quantitative analysis is performed. Interference from hexanal is only likely to be important, however, if very low concentrations of toluene ( $0.1 \text{ mg l}^{-1}$  or less) are to be measured.

In some deaths attributed to the abuse of LPG, only butane, isobutane, and propane are detected on headspace GC of postmortem samples. In other cas-

es, these three compounds are present, but in addition 2-propanol, acetone, 2-methyl-2-propanol, 2-butanol, and/or butanone are present (**Table 5**). By analogy with the metabolism of hexane (**Table 4**), these latter compounds probably arise from the metabolism of the butanes and propane.

The alkyl nitrites that can be abused by inhalation (cyclohexyl nitrite, isobutyl nitrite, isopentyl nitrite) are a special case in that (1) they are extremely unstable and break down rapidly *in vivo* to the corresponding alcohols and (2) usually also contain other isomers (butyl nitrite, pentyl nitrite). Any products submitted for analysis will usually contain the corresponding alcohols as well as the nitrites.

### Interpretation of Quantitative Results

Conversion factors for ambient air conditions (ppm to  $\text{mg m}^{-3}$ ) and for concentrations in blood and other fluids (SI mass to molar units) for a number of volatile compounds are given in **Table 6**. There may be a big overlap in the blood concentrations of volatile compounds attained after workplace exposure and as a result of deliberate inhalation of vapor. For example, blood toluene concentrations after exposure to up to 127 ppm toluene (UK OEL at the time was 100 ppm) for 8 h ranged between 0.4 and

**Table 6** Some volatile compounds: conversion factors

<sup>a</sup> 25°C, 760 mm Hg (data from Bingham E, Cohns B, and Powell CH (eds.) (2001) *Patty's Toxicology*, 5th edn., vol. 9. New York: Wiley). To convert 1 ppm to mg m<sup>-3</sup> multiply by atomic or formula mass and divide by 24.45; to convert 1 mg m<sup>-3</sup> to ppm multiply by 24.45 and divide by atomic or formula mass.

<sup>b</sup> To convert mg l<sup>-1</sup> to µmol l<sup>-1</sup> divide by atomic or formula mass and multiply by 1000; to convert µmol l<sup>-1</sup> to mg l<sup>-1</sup>, multiply by atomic or formula mass and divide by 1000.

6.7 mg l<sup>-1</sup>. After brief exposure only signs of moderate intoxication (e.g., slurred speech, unsteady movements) have been associated with blood toluene concentrations as high as 30 mg l<sup>-1</sup>. Blood toluene concentrations in samples from 132 patients who were thought to have engaged in VSA ranged from 0.2 to 70 mg l<sup>-1</sup>, and were above 5 mg l<sup>-1</sup> in

22 of 25 deaths. On the other hand, 13 patients with blood toluene concentrations greater than 10 mg l<sup>-1</sup> were either asymptomatic or only mildly intoxicated (headache, nausea, vomiting, and/or drowsiness), although these manifestations of toxicity can lead to 'indirect' acute VSA-related death as discussed above. Apart from individual differences in tolerance

and possible loss of toluene from the sample prior to analysis, sample contamination, etc., the lack of a strong correlation between blood concentrations and clinical features of poisoning is probably due to rapid initial tissue distribution and elimination.

About 80% of a dose of toluene is converted to hippuric acid (Table 4). Similarly, more than 90% of a dose of xylene is metabolized to methylhippuric (toluric) acids. The principal isomer found in urine is 3-methylhippurate, since *m*-xylene is the principal component of technical grade xylene (Table 1). Methylhippurates are not normal urinary constituents, but hippuric acid may arise from the metabolism of benzoates in foods and medicines, and thus caution is needed in the interpretation of results. Hippurate and methylhippurate excretion is often expressed as a ratio to creatinine since this obviates the need for 24 h urine collections. Occupational exposure to toluene can give rise to ratios of up to 1 g of hippurate per gram creatinine or more; in patients suspected of VSA, a ratio of more than 1 g of hippurate per gram creatinine strongly suggests, but does not prove, toluene exposure. Measurement of urinary *o*-cresol has been proposed as an alternative means of monitoring toluene exposure selectively, particularly in occupational circumstances, but the assay procedure is relatively complex and is thus not widely used.

## Introduction

The Fourier transform (FT) is ubiquitous in science and engineering. For example, it finds application in the solution of equations for the flow of heat, for the diffraction of electromagnetic radiation, and for the analysis of electrical circuits. The concept of the FT lies at the core of modern

electrical engineering, and is a unifying concept that connects seemingly different fields. The availability of user-friendly commercial computer programs such as Maple<sup>™</sup>, Mathematica<sup>™</sup>, and Matlab<sup>™</sup> allows the FT to be part of every technical person's toolbox. The FT can be used to interpolate functions and to smooth signals. For example, in the processing of pixelated images, the high spatial frequency edges of pixels can easily be removed with the aid of a two-dimensional FT. This article, however, is not about the use of the FT as a tool in applied mathematics, but as the basis for techniques of analytical measurement.

and possible loss of toluene from the sample prior to analysis, sample contamination, etc., the lack of a strong correlation between blood concentrations and clinical features of poisoning is probably due to rapid initial tissue distribution and elimination.

About 80% of a dose of toluene is converted to hippuric acid (Table 4). Similarly, more than 90% of a dose of xylene is metabolized to methylhippuric (toluric) acids. The principal isomer found in urine is 3-methylhippurate, since *m*-xylene is the principal component of technical grade xylene (Table 1). Methylhippurates are not normal urinary constituents, but hippuric acid may arise from the metabolism of benzoates in foods and medicines, and thus caution is needed in the interpretation of results. Hippurate and methylhippurate excretion is often expressed as a ratio to creatinine since this obviates the need for 24 h urine collections. Occupational exposure to toluene can give rise to ratios of up to 1 g of hippurate per gram creatinine or more; in patients suspected of VSA, a ratio of more than 1 g of hippurate per gram creatinine strongly suggests, but does not prove, toluene exposure. Measurement of urinary *o*-cresol has been proposed as an alternative means of monitoring toluene exposure selectively, particularly in occupational circumstances, but the assay procedure is relatively complex and is thus not widely used.

## Introduction

The Fourier transform (FT) is ubiquitous in science and engineering. For example, it finds application in the solution of equations for the flow of heat, for the diffraction of electromagnetic radiation, and for the analysis of electrical circuits. The concept of the FT lies at the core of modern

electrical engineering, and is a unifying concept that connects seemingly different fields. The availability of user-friendly commercial computer programs such as Maple<sup>TM</sup>, Mathematica<sup>TM</sup>, and Matlab<sup>TM</sup> allows the FT to be part of every technical person's toolbox. The FT can be used to interpolate functions and to smooth signals. For example, in the processing of pixelated images, the high spatial frequency edges of pixels can easily be removed with the aid of a two-dimensional FT. This article, however, is not about the use of the FT as a tool in applied mathematics, but as the basis for techniques of analytical measurement.

## Fourier's Integral Theorem

Fourier's integral theorem is a remarkable result:

$$F(v) = \int_{-\infty}^{\infty} f(t) e^{-i2\pi vt} dt \quad [1]$$

and

$$f(t) = \int_{-\infty}^{\infty} F(v) e^{+i2\pi vt} dv \quad [2]$$

where  $F(v)$  is the FT of an arbitrary time-varying function  $f(t)$  and  $i = \sqrt{-1}$ . We adopt the notation of lower case letters for a function,  $f(t)$ , in the time domain and upper case letters for the corresponding Fourier-transformed function,  $F(v)$ , in the frequency domain. The variable  $v$  is the frequency in units of hertz ( $s^{-1}$ ). The second eqn [2] defines the inverse FT that yields the original function,  $f(t)$ . Equations [1] and [2] can be written in many ways, but the version above is convenient for practical work because of the absence of factors (e.g.,  $1/2\pi$ ) in front of the integrals. These factors can be an annoying source of errors in the computation of FTs. The variables  $t$  and  $v$  can be replaced by any reciprocal pair (e.g.,  $x$ , in cm, for optical path difference and  $\tilde{\nu}$ , in  $cm^{-1}$ , for wavenumber in an infrared FT spectrometer) as long as their product is dimensionless.

The exponential in eqn [2] can be expanded as

$$e^{i2\pi vt} = \cos(2\pi vt) + i \sin(2\pi vt) \quad [3]$$

to give

$$f(t) = \int_{-\infty}^{\infty} F(v) \cos(2\pi vt) dv + i \int_{-\infty}^{\infty} F(v) \sin(2\pi vt) dv \quad [4]$$

The simple physical interpretation of eqn [4] is that any arbitrary (not necessarily periodic!) function  $f(t)$  can be expanded as an integral ('sums') of sine and cosine functions, with  $F(v)$  interpreted as the amplitudes of the 'waves.' The necessary amplitudes  $F(v)$  can be obtained from eqn [1], which thus represents the frequency analysis of the arbitrary function,  $f(t)$ . In other words, eqn [1] analyses the function  $f(t)$  in terms of its frequency components and eqn [2] puts the components back together again to recreate the function. Notice that if  $f(t)$  is an even function (i.e.,  $f(-t) = f(t)$ ), then the cosine transform suffices (i.e., only first term on the right hand side of eqn [4] need be retained), but this is rarely the case in practice.

## Fourier Transforms

The FT can be applied to a number of simple functions as presented in pictorial form in **Figure 1**. The FT of a Gaussian is another Gaussian, the decaying exponential (double-sided) gives a Lorentzian, and the boxcar function gives a sinc(=  $\sin(x)/x$ ) function.

The FTs of a number of elementary functions require the use of the delta function,  $\delta(v - v_0)$ . The  $\delta(v - v_0)$  function has the 'sifting' property,

$$f(v_0) = \int_{-\infty}^{\infty} \delta(v - v_0) f(v) dv \quad [5]$$

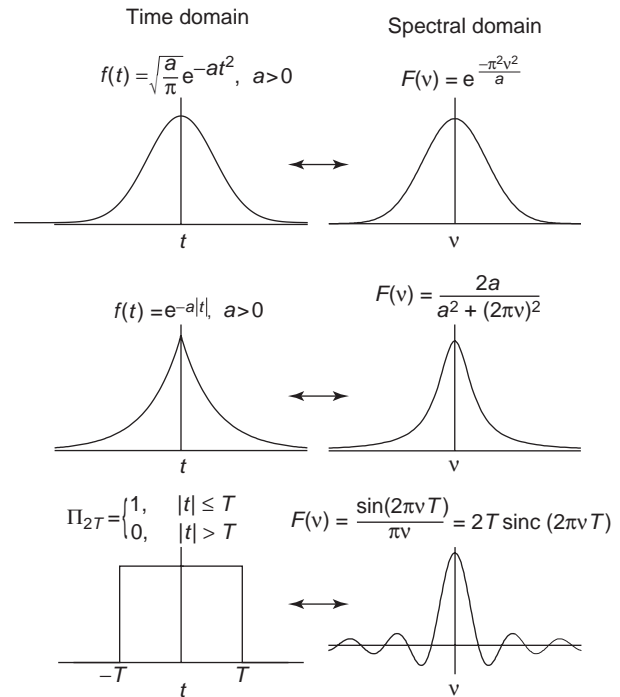

that implies unit area,

$$1 = \int_{-\infty}^{\infty} 1 \cdot \delta(v - v_0) dv \quad [6]$$

and a value of 0 for  $v \neq v_0$ .

The FT of the infinitely long wave,  $\cos(2\pi v_0 t)$ , is thus,  $(\delta(v - v_0) + \delta(v + v_0))/2$ , which has a value of  $\infty$  when  $v = v_0$  and  $v = -v_0$ . The appearance of negative frequencies is at first surprising, but is required by the mathematics of complex numbers. The identity

$$\delta(v - v_0) = \int_{-\infty}^{\infty} e^{\pm i2\pi(v-v_0)t} dt \quad [7]$$

**Figure 1** The Fourier transforms of Gaussian, double-sided exponential, and boxcar functions.

can be interpreted as the infinite sum of waves all phased to add up at  $\nu = \nu_0$  and to cancel for  $\nu \neq \nu_0$ . No function in the usual sense can be infinitely high, infinitely narrow and still have unit area. In mathematics, the delta function is thus defined as the limit of a series of peaked functions such as Gaussians.

While the FT of the even cosine function is real, the result for  $\sin(2\pi\nu_0 t)$  is imaginary:  $(\delta(\nu - \nu_0) + \delta(\nu + \nu_0))/(2i)$ . Since the sine function is  $90^\circ$  out of phase to the corresponding cosine, it is clear that the imaginary axis is used to keep track of phase shifts, consistent with the polar representation of a complex number:  $x + iy = re^{i\phi}$  with  $r = \sqrt{x^2 + y^2}$  and  $\phi = \tan^{-1}(y/x)$ . In this phasor picture, positive and negative frequencies can be interpreted as clockwise and counterclockwise rotations in the complex plane.

The FT has many useful mathematical properties including linearity, and using eqn [2], the derivative  $df(t)/dt$  has the transform  $(i2\pi\nu)F(\nu)$ . The convolution theorem is particularly useful because it relates the product of two functions,  $F(\nu) \cdot G(\nu)$ , in the frequency domain to the convolution integral

$$f * g(t) \equiv \int_{-\infty}^{\infty} f(\tau)g(t - \tau) d\tau \quad [8]$$

in the time domain (or vice versa), using the upper case/lower case FT notation for the  $(F(\nu), f(t))$ ,  $(G(\nu), g(t))$  pairs. For example, a finite piece of a cosine wave represented by the product,  $\cos(2\pi\nu_0 t)\Pi_{2T}(t)$ , leads to the convolution (Figure 1) of two delta functions with a sinc function in the frequency domain. The result is,  $T\text{sinc}(2\pi T(\nu - \nu_0)) + T\text{sinc}(2\pi T(\nu + \nu_0))$ , i.e., the infinitely narrow  $\delta$ -functions at  $\pm \nu_0$  produced by the FT of the infinite cosine have been broadened into sinc functions for the more realistic case of a finite length cosine wave. Similarly, the FT of the double-sided decaying exponential wave,  $\cos(2\pi\nu_0 t)\exp(-a|t|)$ , is two Lorentzians centered at  $\pm \nu_0$  (Figure 1) in the frequency domain.

## Discrete Fourier Transform

The trouble with practical applications of Fourier's integral theorem is that it requires continuous functions for an infinite length of time. These conditions are clearly impossible, so the case of a finite number of observations must be considered. Consider sampling the data every  $\Delta t$  for  $2N$  equally spaced points from  $-N$  to  $N-1$  with  $t_j = j\Delta t$ ;  $j = -N, -N+1, \dots, 0, \dots, N-1$ . The FT, eqn [1], then becomes the discrete FT:

$$F(\nu) = \Delta t \sum_{j=-N}^{N-1} f(j\Delta t)e^{-i2\pi\nu j\Delta t} \quad [9]$$

The question immediately arises as to the number of points required to sample the signal  $f(t)$ . If not enough points are taken the signal will be distorted, and if too many points are used there is a waste of resources. The answer is a remarkable result due to Nyquist: given a signal with no frequency components above  $\nu_{\max}$ , the signal can be completely recovered if it is sampled at a frequency of  $2\nu_{\max}$  (or greater). The Nyquist (or critical) sampling at  $2\nu_{\max}$  corresponds to two data points per wavelength for the frequency component at  $\nu_{\max}$ . It seems almost magical that such sparse, minimal sampling allows exact recovery of the original signal by interpolation. The connection between the time and the frequency domains for critically sampled data is illustrated in Figure 2. In the time domain, the interferogram is recorded from  $-T$  to  $T$  with a point spacing  $\Delta t = 1/(2\nu_{\max})$ , while in the spectral domain the data is present from  $-\nu_{\max}$  to  $\nu_{\max}$  with a frequency point spacing of  $\Delta\nu = 1/(2T)$ . In the particular case of an even function, although  $2N$  points ( $2N = 2T/\Delta t = 2\nu_{\max}/\Delta\nu$ ) are displayed in Figure 2, only  $N$  of them are independent. The discrete inverse FT is

$$f(t) = \Delta\nu \sum_{k=-N}^{N-1} F(k\Delta\nu)e^{i2\pi kt\Delta\nu} \quad [10]$$

Figure 2 Nyquist sampling in the spectral and time domains.

with  $t$  only given at  $t_j = j\Delta t$  in eqn [10] and  $v$  given at  $v_k = k\Delta v$  in eqn [9].

Undersampling a signal is unfortunately a common occurrence and causes aliasing. A simple example of aliasing is the observation on television of a wheel on a wagon or a car rotating ‘backwards’ as the vehicle moves forward. For television in the USA, motion picture cameras sample the image at 30 times per second (the frame rate) and the image of the rotating wheel is thus often undersampled. When the sampling frequency  $v_s$  is somewhat less than the required  $2v_{\max}$ , then the spectrum between  $v_s/2$  and  $v_{\max}$  is ‘folded back’  $\sim v_s/2$  and appears as a reversed artifact between  $-v_s/2$  and  $v_s/2$ . If the signal is very undersampled, then it can be folded (aliased) many times (like fan-folded printer paper) between  $-v_s/2$  and  $v_s/2$ . This folding of the spectrum  $\sim v_s/2$  is called aliasing.

Aliasing can sometimes be used to advantage. For example, if a spectrum has no signal between 0 and  $v_{\max}/2$ , then every second point can be deleted (‘decimation’) because this undersampling by a factor of 2 will fold the signal from  $v_{\max}/2$  to  $v_{\max}$  backwards into the empty region from 0 to  $v_{\max}/2$ .

The discrete FT, eqn [9], can be evaluated in a brute force fashion on a computer using the available sine and cosine functions, eqn [3], but this method is very slow for a large number of points. The FT algorithm of Cooley and Tukey is much faster. The derivation of the Cooley–Tukey algorithm (‘fast Fourier transform’) starts by rewriting the exponent in eqn [10] as

$$i2\pi tk\Delta v = i2\pi j\Delta t k\Delta v = i\pi jk/N \quad [11]$$

using

$$t_j = j\Delta t; \quad j = -N, \dots, N-1 \quad \text{and} \quad \Delta t\Delta v = \Delta t/(2T) = 1/(2N) \quad [12]$$

The discrete FT and inverse FT, eqns [9] and [10], thus become:

$$\begin{aligned} F(v_k) &= \Delta t \sum_{j=-N}^{N-1} f(j\Delta t) e^{-i\pi jk/N} \\ &= \Delta t \sum_{j=0}^{2N-1} f(j\Delta t) e^{-i\pi jk/N} \end{aligned} \quad [13]$$

$$\begin{aligned} f(t_j) &= \Delta v \sum_{k=-N}^{N-1} F(k\Delta v) e^{i\pi jk/N} \\ &= \Delta v \sum_{k=0}^{2N-1} F(k\Delta v) e^{i\pi jk/N} \end{aligned} \quad [14]$$

and the limits of the summation are shifted from  $-N$  to  $N-1$  to 0 to  $2N-1$  by considering the  $f(t)$  from  $-T$  to  $T$  and  $F(v)$  from  $-v_{\max}$  to  $v_{\max}$  as periodic functions (Figure 3). The fast FT requires  $2N$  to be a power of two, i.e.,  $2^m$  so the data are padded with zeros up to the next highest power of 2. The algorithm works by repeatedly ( $m$  times) dividing a  $2N$ -point transform into two smaller  $N$ -point transforms. The resulting final transform has  $2N$  points in the frequency domain, with the first  $N$  covering 0 to  $v_{\max}$ . The second  $N$  points from  $v_{\max}$  to  $2v_{\max}$  are the aliased points from  $-v_{\max}$  to 0 (see Figure 3).

The fast FT allows optimal interpolation of data. The original  $N$  points are folded  $\sim 0$  to make  $2N$  points and are then shifted by  $+N$  (Figure 3). The fast FT then creates  $2N$  points in the frequency domain, which are padded by the desired number of extra zeros in the appropriate location in the middle (e.g.,  $6N$  zeros in total for fourfold interpolation) and transformed back. (The extra zeros are added in the middle because of the aliasing of points from  $-v_{\max}$  to 0 into  $v_{\max}$  to  $2v_{\max}$  as shown in Figure 3.) This procedure creates interpolated points between the original data points.

**Figure 3** Frequency and time domains with the signals considered to be periodic.

## Fourier Transform Spectroscopy

Spectra are traditionally recorded by dispersing the radiation and measuring the absorption or emission, one point at a time. In some regions of the spectrum, for which tunable radiation sources are available, one can imagine stepping the frequency of the source from  $\nu_n$  to  $\nu_{n+1}$  by  $\Delta\nu$  (Figure 2) and recording the absorption. The primary attraction of FT techniques as compared to the 'traditional' approach is that all frequencies in the spectrum are detected at once. This property is the so-called multiplex or Fellgett advantage of FT spectroscopy.

Most FT measurements at long wavelengths (e.g., Fourier transform nuclear magnetic resonance (FT-NMR)) are made by irradiating the system with a short broadband pulse capable of exciting all the frequency components of the system, and then monitoring the free induction decay response. Such an approach presumes the availability of a coherent, high-power source of radiation that covers the entire spectral region of interest. A simple free induction decay has

$$f(t) = e^{-at} \cos(2\pi\nu_0 t), \quad t \geq 0, \quad a > 0$$

and

$$f(t) = 0, \quad t < 0 \quad [15]$$

with the corresponding spectrum

$$F(\nu) = \frac{1}{2(a + i2\pi(\nu - \nu_0))} + \frac{1}{2(a + i2\pi(\nu + \nu_0))} \quad [16]$$

If  $\nu \approx \nu_0$  and  $a \ll \nu_0$ , then the second term of eqn [16] can be dropped to give

$$F(\nu) = \frac{a}{2(a^2 + 4\pi^2(\nu - \nu_0)^2)} - \frac{i2\pi(\nu - \nu_0)}{2(a^2 + 4\pi^2(\nu - \nu_0)^2)} \quad [17]$$

The real part of  $F(\nu)$  is a Lorentzian centered at  $\nu_0$  (first term on the right of eqn [17]), while the imaginary part (second term on the right of eqn [17]) is the corresponding dispersion curve (Figure 4). The constant  $1/a$  is the lifetime  $\tau$  of the decay and the full width at half maximum of the Lorentzian is  $a/\pi$ .

As compared to a double-sided even function, it is the abrupt turn-on of the free induction decay at  $t = 0$  that causes the large imaginary signal. All causal signals (defined to have  $f(t) = 0$  for  $t < 0$ ) have this property. The physical interpretation is that the abrupt start of the signal excites an in-phase response (the real part) to the cosine part of the original excitation wave as well as a response  $90^\circ$  out of phase (the imaginary part). The antisymmetric imaginary part is needed to cancel the symmetric real

Time domain

$$f(t) = \begin{cases} e^{-at} \cos(2\pi\nu_0 t), & t \geq 0, \quad a > 0 \\ 0, & t < 0 \end{cases}$$

Frequency domain

$$\text{Re}\{F(\nu)\} = \frac{a/2}{a^2 + 4\pi^2(\nu - \nu_0)^2}$$

$$\text{Im}\{F(\nu)\} = \frac{-\pi(\nu - \nu_0)}{a^2 + 4\pi^2(\nu - \nu_0)^2}$$

Figure 4 Fourier transform of a free induction decay.

part for  $t < 0$ . The large imaginary frequency component means that typically the magnitude spectrum is computed as

$$|F(\nu)| = \sqrt{(\text{Re}\{F(\nu)\})^2 + (\text{Im}\{F(\nu)\})^2} \quad [18]$$

for practical applications in, for example, FT mass spectrometry.

As usual there is a reciprocal relationship between the time domain and the frequency domain. The more rapid is the damping (decay) of the signal (i.e., larger  $a$  and shorter lifetime  $\tau = 1/a$ ), the wider the Lorentzian and dispersion lineshape functions become in the spectral domain (Figure 4).

At higher frequencies, FT spectroscopy is generally carried out with a Michelson interferometer rather than by detection of a coherent transient decay. The Michelson interferometer divides the input radiation into two parts with a beamsplitter and then recombines them. As the optical path difference of the two parts is varied, the interference of the recombined beams produces an interferogram. If the optical path difference,  $x$ , changes at a constant rate,  $\nu$ , then the interferogram becomes a function of time,  $f(x) = f(\nu t)$ , and the FT yields the desired spectrum,  $F(\nu)$ . In general, double-sided interferograms are

recorded from  $-L(=-\nu T)$  to  $+L(=\nu T)$  in optical path difference, as shown in **Figure 2**. For practical reasons, to save resources sometimes, only a short double-sided interferogram is recorded to determine the phase. This low-resolution-phase function is then interpolated to generate a high-resolution-phase function and applied to a high-resolution single-sided spectrum recorded only from 0 to  $L$ , rather than from  $-L$  to  $+L$ .

The main barrier to the use of free induction decay for FT spectroscopy in the infrared region is the lack of a convenient powerful source of broadband coherent radiation. In addition, the decay times for the coherently excited polarization in the system tend to be very short at higher frequencies. Coherent terahertz spectrometers operating in the far infrared region are now practical because of the success of ultrafast laser technology in generating broadband terahertz pulses.

FT techniques are inherently digital and were not practical before the advent of the digital computer. The digital data can thus be filtered and manipulated with ease. In particular, the instrumental resolution can be varied at will and chosen to match the inherent resolution of the physical system. As shown in **Figure 2**, recording the interferogram for a longer time  $T$  (longer optical path difference for a Michelson interferometer) results in a closer point spacing  $\Delta\nu = 1/(2T)$  and higher instrumental resolution in the frequency domain. There are practical limits because when the interferometric signal is no longer visible because it is buried in noise, no further increase in resolution is possible. The FT spectrometer can thus easily trade decreased spectral resolution for increased signal-to-noise ratio. Very high instrumental resolutions are possible and resolving powers,  $R \equiv \nu/\Delta\nu$ , in excess of  $10^6$  can be achieved in the visible and infrared spectral regions, and for mass spectrometry.

When FT spectroscopy is implemented with a Michelson interferometer, there is an additional advantage over a grating or prism spectrograph that uses rectangular slits. The circular entrance aperture of the Michelson interferometer can be opened until the subtended solid angle,  $\Omega_{\max}$ , (in steradians, as measured using the distance to the collimator) is given by  $R\Omega_{\max} = 2\pi$ , with resolving power,  $R$ , computed for the highest measured frequency  $\nu_{\max}$ . For the same resolving power, a grating spectrograph typically has 50–100 times smaller  $\Omega_{\max}$  as subtended by the slits. Much more radiation can thus enter the larger entrance aperture of a FT spectrometer than a grating spectrometer, as was first pointed out by Jacquinot. The throughput or Jacquinot advantage is always operative for a Michelson interferometer.

Surprisingly, the multiplex ‘advantage’ of FT spectroscopy is not always available and depends on the principal noise source in the system. At low frequencies, the principal noise source is often detector or background noise. In this case, the noise is independent of the signal level and is constant. Compared to a single element detector used to detect a single frequency interval,  $\Delta\nu$ , the signal level for the FT spectrometer that detects  $N$  channels of width  $\Delta\nu$  is  $N$  times greater. The noise in these  $N$  channels also now appears at the detector, but because of partial cancellation due to the random nature of noise (mean value of zero), the noise level increases by only  $\sqrt{N}$ . Note that true noise always partially cancels in this manner but that signal artifacts (‘periodic noise’) will not generally do so. Overall then the signal-to-noise ratio has improved by  $\sqrt{N}$  for a FT spectrometer.

To higher frequencies, in the visible region, photons carry more energy and can be detected, for example, by counting. The noise in such a system is typically due to ‘shot’ noise arising from the Poisson statistics of random fluctuations in the arrival times of photons at the detector. Shot noise is proportional to the square root of the number of photons arriving at the detector. If the primary noise source is shot noise, then the noise is proportional to the square root of the signal level. In this case, for the  $N$ -channel FT spectrometer the signal level increases by  $N$  and the noise increases by  $\sqrt{N}$  for the increased number of channels and another factor of  $\sqrt{N}$  for the increased intensity. Overall there is no change in the signal-to-noise ratio as compared to a single channel spectrometer. Surprisingly then, in the visible region the multiplex advantage usually does not apply, although the throughput and ‘digital’ advantages remain.

Unfortunately, there is a third possibility for the noise. In remote sensing applications in the earth’s atmosphere or in astronomy, the noise may be directly proportional to the signal level. Transmission through the atmosphere has random fluctuations (‘scintillations’) that are analogous to ‘ $1/f$ ’ noise that appears in electronic circuits at low frequency. In the laboratory, emission from a sample may be excited by a laser or other source that is plagued by amplitude fluctuations. There may also be a weak molecular emission of interest in a spectrum dominated by strong fluctuating lines from an extraneous atom or molecule. In all these cases, the  $N$ -channel FT spectrometer increases the signal by  $N$  over a single channel spectrometer, but the noise also increases by another factor of  $\sqrt{N}$  for the increased number of channels and by  $N$  because of the increased intensity level. Incredibly, the signal-to-noise ratio has therefore decreased by  $\sqrt{N}$  and there is a multiplex

‘disadvantage’ for a FT spectrometer. Because the FT spectrometer detects the entire spectrum (including the noise) at one time, the noise from all the channels is distributed throughout the spectrum. In a simple single channel spectrometer, only the noise from that single channel appears, even though nearby channels may have strongly fluctuating signals. It is this redistribution of noise from all channels that causes the Fourier disadvantage.

The presence of a multiplex disadvantage accounts for the enormous success of small multichannel visible spectrometers based on array detectors, as compared to low resolution visible FT spectrometers. In any case, for a particular application a careful analysis of the noise is indispensable for an optimum instrument.

## Fourier Transform Applications

The FT technique has been applied in a multitude of different areas. Starting at low frequencies, FT methods have been used for dielectric response spectroscopy of solids (sometimes called time domain reflectometry). A short picosecond voltage pulse is applied to a dielectric and the current response is measured. Fourier transformation of the current gives the dielectric response function,  $\epsilon(\nu)$ , which is typically interpreted as the Debye relaxation of dipoles.

The main application at low frequencies is, of course, NMR. In FT-NMR, a magnetized sample is irradiated by radio frequency (RF) radiation to manipulate the bulk magnetization. The basic signal is the free induction decay, but hundreds of sophisticated RF pulse sequences have been invented for specific purposes, including medical imaging.

A related RF technique to NMR is nuclear quadrupole resonance (NQR). In NQR, transitions between nuclear quadrupole levels of nuclei in a solid material are induced by the applied radiation. The electric field gradients in the solid orient the quadrupolar nuclei ( $I > 1/2$ ) and give rise to quantized energy levels that yield transitions in the MHz range. FT-NQR spectroscopy measures these splittings and the relaxation times by free induction decay or various pulse echo experiments. FT-NQR spectroscopy provides information about the local environment around the quadrupolar nucleus in a crystal.

Electron spin resonance (ESR) operates at somewhat higher frequencies in the GHz range and is sometimes called electron paramagnetic resonance (EPR). ESR is like NMR but uses electron spins rather than nuclear spins. By definition, FT-ESR studies free radicals, and it is more sensitive than FT-NMR but of less general applicability. Related to

ESR is muon spin resonance ( $\mu$ SR), carried out at high-energy accelerator sources such as TRIUMF (Vancouver, Canada) that provide muons.

In the gigahertz region, FT-microwave experiments were pioneered by the late W.H. Flygare. FT-microwave experiments use a short pulse of microwave radiation to polarize a gaseous sample in a waveguide or, more commonly, in a Fabry–Perot cavity. Free induction decay is detected and Fourier transformed into a spectrum. FT-microwave spectroscopy of cold molecules in pulsed jet expansion is particularly popular because of the increased sensitivity associated with low temperatures, and the possibility of studying large molecules and van der Waals complexes.

In the infrared, visible, and near ultraviolet regions, FT methods generally use the Michelson interferometer rather than detecting a free induction decay. The practical short wavelength limit for the Michelson interferometer is  $\sim 170$  nm. There is no hard long wavelength limit, and measurements down to a few  $\text{cm}^{-1}$  are possible. Recently, coherent time domain terahertz spectroscopy has become possible in the far infrared region. In this case, the system is polarized with an ultrashort pulse of terahertz radiation and the coherent decay is detected using ultrafast laser techniques.

FT techniques have also been applied with great success to mass spectrometry. The ion cyclotron resonance (ICR) spectrometer traps ions in a magnetic field. The ions travel in circles about the applied magnetic field (cyclotron motion) and are trapped in the direction along the magnetic field by small voltages applied to the end caps of the trapping cell. A short pulse of RF radiation coherently phases the ions in the trap and increases their orbits. The phase-coherent orbiting ions induce small image currents on the two opposite metal walls of the trapping cell. The FT of these image currents yields the mass spectrum. In this case, the decay time of the free induction decay signal can be very long because the dephasing of the cyclotron motion of the ions in a homogenous magnetic field is controlled by collisions with residual gas. The FT-ICR technique can thus have ultrahigh mass resolution and great sensitivity.

### Introduction

Analysis of gaseous fuels is necessary for quality control. The most important quality criteria are the calorific value (CV) and the sulfur (S) content. The CV is related to the quantity of heat energy, which is liberated when the fuels are burned; the sulfur

content gives information concerning the potential for sulfur dioxide (SO<sub>2</sub>) formation, which must be limited for environmental reasons. The major types of gaseous fuels are natural gas, processed gas, e.g., coal gas, and blends of both. The CV and the total sulfur content can be determined as sum parameters (i.e., without knowledge of individual compounds) or by analyzing the fuel and calculating the CV and the sulfur content from the composition. This article provides a survey of the methods of gaseous fuel analysis with regard to online and offline analysis and special techniques.

### General Methods

Fuel gases consist of combustible compounds like hydrocarbons, hydrogen (H<sub>2</sub>), and carbon monoxide

(CO), which are the source of energy, and of incombustible compounds like helium (He), nitrogen (N<sub>2</sub>), and carbon dioxide (CO<sub>2</sub>), which decrease the specific energy content. Sulfur-containing compounds are in the gas as natural contaminants and odorants. In a refined fuel gas their concentrations are normally in the µl per l range and do not make a significant contribution to the CV. Traditionally CV and sulfur content are determined as sum parameters. Therefore a known quantity of the gas is burned in an excess oxygen atmosphere under exactly defined conditions. To obtain the CV, this burning takes place in a combustion calorimeter: the reaction enthalpy is absorbed in a known amount of fluid and the temperature rise of this fluid is measured. So it is generally possible to determine the CV. Operating a combustion calorimeter is difficult, because the parameters temperature, pressure, gas, and fluid volume have to be measured very accurately. Minor changes in ambient conditions can dramatically affect the result. To prevent this, many technical resources are necessary. Moreover, combustion calorimeters are very expensive and incur high costs during operation. To determine the total sulfur content, the sample is burned in oxyhydrogen in a *Wickbold* apparatus by Wickbold method to determine sulfur in fuels by oxidation to form sulfur dioxide according to DIN 51409. Sulfur dioxide is formed and hydrogen peroxide is added to create sulfate anions; their concentration is determined by titrimetric methods. This analysis is very difficult and time consuming, with poor precision and reproducibility. There are other methods for total sulfur determination, based on the principle of burning the fuel sample and measuring the concentration of the SO<sub>2</sub> formed by gas chromatography or luminescence detection.

However, none of the burning methods gives any information about individual compounds. To overcome these problems and following the development and proven efficacy of gas chromatography in many other fields, this technique was introduced in fuel analysis. Now it has been possible to determine individual compounds and to calculate the integral parameters of density, compressibility, *Wobbe*-index, the volumetric basis superior calorific value at specified reference conditions divided by the square root of the relative density at the same reference conditions. etc. from physical properties of the pure compounds. So such analysis became a powerful tool for gas quality control to ensure that gas distributors deliver the contracted heat energy to their customers. The gas chromatographs (GCs) can be operated online using process GCs or offline using laboratory GCs. Online operation means installation of the GCs

near the 'production process', i.e. near the drilling hole, at the pipeline in the delivery point or in the refinery plant and implies fully automatic operation 24 hours a day even under extreme ambient conditions. Offline operation means that a qualified person operates the instrument in any control station or in an analytical laboratory.

## Instrumentation

### Gas Chromatographs

Basic components of GCs are the sample injector, the separation column(s), switching valves, detector(s), and a computer system for evaluating and reporting the results. Process GCs are equipped and tuned to analyze the same type(s) of fuel in a very short analysis time with high accuracy and reliability and they must be able to calibrate themselves. Modern process GCs are operated using a personal computer (PC) connected directly to the control unit or via a telephone link. The PC may be connected directly to the control unit of the GC or via modem and telephone lines. If necessary, the operator can carry out operation, communication, and diagnosis from a remote location such as a control laboratory. It is also possible to retrieve all data from the controller and generate reports and chromatograms on a printer/plotter connected to the PC or GC.

The requirements of a laboratory GC are different from those of a process GC. The need for accuracy and reliability is the same but ambient conditions, analysis time, and remote control are less important. More crucial are high analytical performance, flexibility, and smooth operation because laboratory GCs are used to analyze a wide spectrum of gaseous fuels like natural gases of different origin and their substitutes.

Obviously, the chromatographic principles are the same in process and laboratory GCs and they are built up in a very similar way. Standard detectors are in each case the thermal conductivity detector (TCD), which is a universal detector for all components, and the flame ionization detector (FID), which is a specific detector for hydrocarbons. To detect sulfur gases selective detectors like an electrochemical detector, chemiluminescence detector and, most important, flame photometric detector (FPD) are used. Gaseous fuels like natural gas, synthetic gases, and blends are complex mixtures that cannot completely be separated in a single column. Two or more different columns must be combined. To monitor the fuel quality a quasi-continuous analysis is necessary; this means that very short cycle times must be realized. To do so, high-boiling components are removed

from the system by backflushing. To distribute the components to different columns and to backflush any column, special switching techniques which must correspond with the chromatographic system are necessary. Multiport valves are normally used together with packed columns whereas 'valveless' techniques like *Deans*- and *Live*-switching are preferably used together with capillary columns. Advantages of the 'valveless' techniques are low dead volume, no movable parts in the chromatographic path, and no polymer and adsorptive surfaces to cause memory effects and peak broadening. These properties are essential to achieve high resolution with capillary columns.

## Separation Columns

Traditional gaseous fuel analysis is based on packed columns. Multidimensional chromatography, i.e. the use of columns with different retention characteristics coupled in series in one GC system, improves resolution of complex samples. But packed-column systems are not normally able to separate all compounds. To obtain more precise information about the composition of a gas sample, capillary columns were introduced in fuel analysis. The first were wall-coated open tubular (WCOT) columns with a nonpolar methylsilicone as stationary phase for hydrocarbon separation. However, the permanent gases were still separated in packed columns containing cross-linked polystyrene carbosieve, and molecular sieve as separation phases.

With the introduction of the so-called porous layer open tubular (PLOT) columns a new epoch of gas analysis began. PLOT columns are capillary columns with a very high resolution capability. The dimensions are ~10 to 50 m in length (standard length: 25 or 30 m) and 0.32 or 0.53 mm in internal diameter. The increased resolution of these columns can be quantified by the theoretical plate number, which is in the range of 500 to 1000 (packed columns: 100 to 300) theoretical plates per meter of column. The separation mechanism is based on gas-solid chromatography, which is different from gas-liquid chromatography in silicone-oil coated columns. The high activity of the solid adsorbent in PLOT columns causes an intensive and selective retention force.

Typical adsorbents in PLOT columns are, similar to packed columns, aluminum oxide, molecular sieve, and modified cross-linked porous polymers. Aluminum oxide is a very selective stationary phase and it enables the separation of all C<sub>1</sub>- to C<sub>4</sub>-hydrocarbons according to C-number, structure, and degree of saturation. The high surface activity is

combined with a very strong adsorption of polar substances like sulfur gases, water, etc., which change the polarity and thereby the separation characteristics of the column. Molecular sieve separates the noble gases, hydrogen, oxygen, nitrogen, methane (CH<sub>4</sub>) and carbon monoxide without cooling the column, but the retention is affected even by low concentrations of polar gases, which are adsorbed on the surface. Porous polymers are much more resistant. They are ideal for separating carbon dioxide from the permanent gases, light hydrocarbons, and water. The separation behavior can be influenced by generating polar groups in the polymer material. The favorable properties of the porous polymer, molecular sieve, and methyl-silicone columns and the excellent resolution, especially if combined with a temperature program, has made them standard materials in gas analysis. To exemplify the relevance of the instrumentation and column characteristics for gaseous fuel analysis, representative analytical methods with packed and capillary columns are described below.

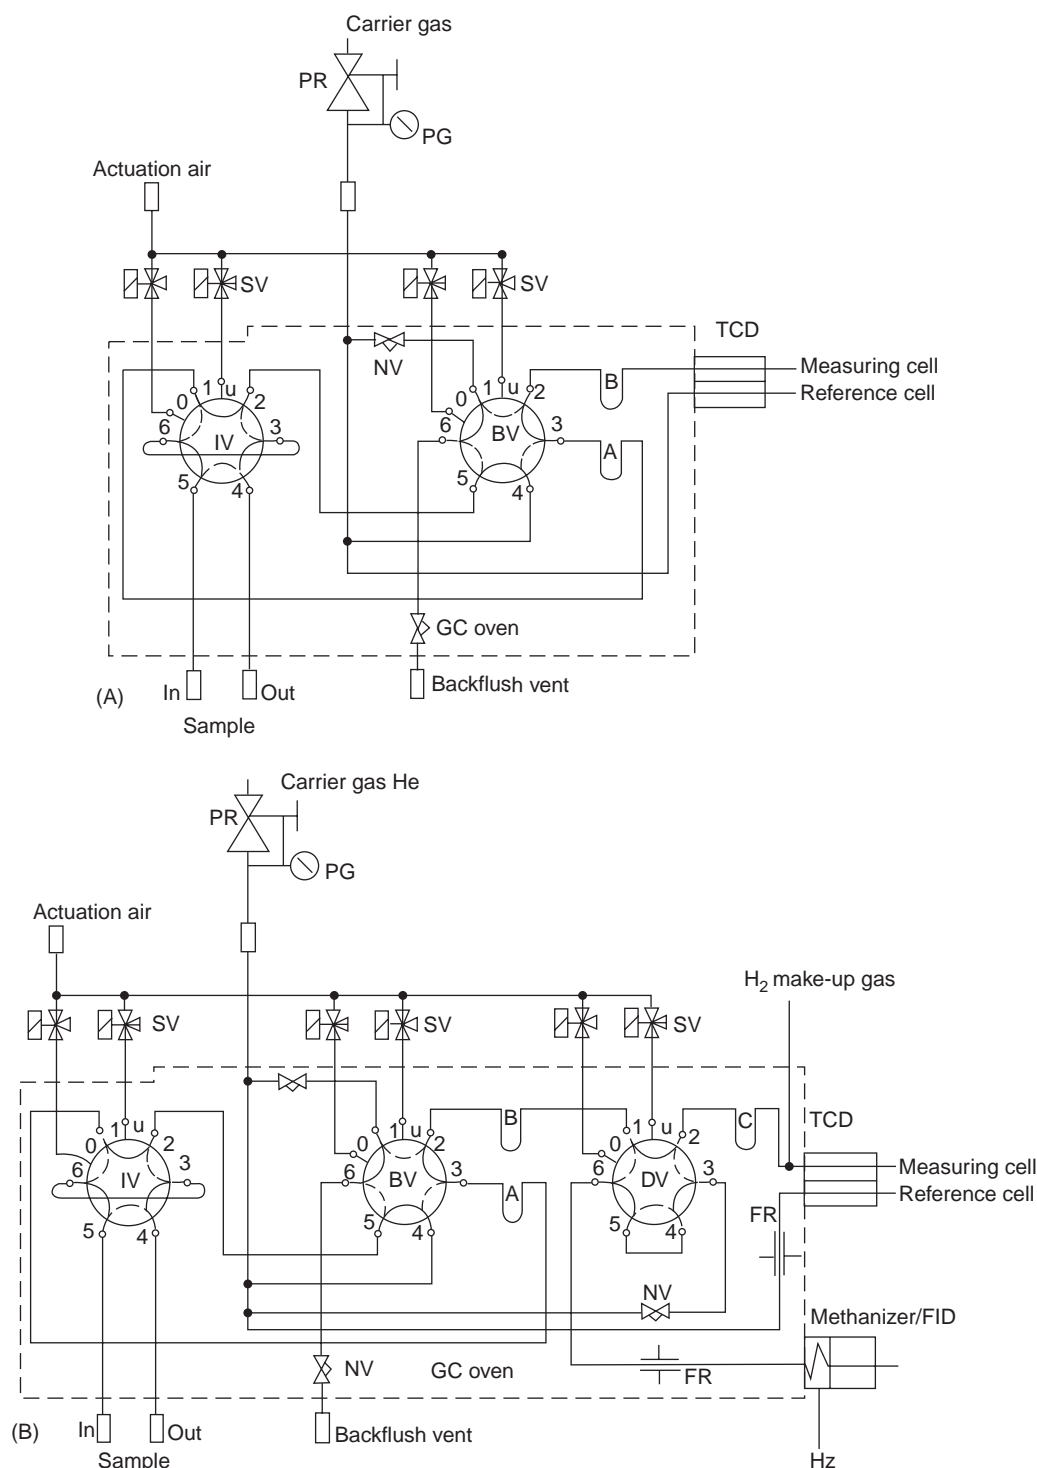

## CV Determination in Gaseous Fuel

### Analysis with Packed Columns

Gaseous fuels may be quite different in composition and therefore no universal analytical method exists. Particularly in process chromatography, only the most interesting compounds are individually determined, to obtain short cycle times. Less important compounds are neglected or determined as a sum peak. There are a number of different analytical methods.

International Standard ISO 6569-1981 describes a rapid natural gas analysis of samples during exploration consisting of a gas sampling valve, two packed columns which are filled with Porapak Q and Porapak T material as stationary phase. Porapak Q and Porapak T are porous polymers of different polarity. Detection is by a TCD and helium is used as carrier gas. The measured compounds N<sub>2</sub>, CO<sub>2</sub>, C<sub>1</sub>- to C<sub>4</sub>-hydrocarbons, and hydrogen sulfide (H<sub>2</sub>S) can be detected sensitively because of the big differences between their thermal conductivities and of the carrier gas helium. A disadvantage is that oxygen is not separated from nitrogen and contamination of the sample by air will give a value for the nitrogen content which is too high.

The GC system is shown schematically in **Figure 1A**. The backflush function (valve BV) is typical and essential for process analysis. It is necessary for conditioning the GC system and removing high-boiling hydrocarbons backwards from the first column (A)

**Figure 1** Packed column systems with six-port valves: (A) system with backflush capability; (B) system with backflush and column switching capability. PR, pressure regulator; PG, pressure gauge; SV, solenoid valve; NV, needle valve; IV, injection valve; BV, backflush valve; DV, distribution valve; A/B/C, column A/B/C; FR, flow restrictor.

within analysis time. In laboratory GCs the backflush function is not always installed; in this case high-boiling compounds are eluted by a temperature program. A typical chromatogram is shown in

**Figure 2.** If a natural gas is blended with a coal gas for instance, the GC system described above is not sufficient, because hydrogen and carbon monoxide are present. For this analysis an extended system is

**Figure 2** Thermal conductivity detector chromatogram from a packed column system, temperature programmed according to ISO 6974–1984.

necessary, shown in **Figure 1B**: the additional molecular sieve column (C) allows the separation of hydrogen, oxygen, nitrogen, methane, and carbon monoxide. To overcome the anomaly in thermal conductivity of helium/hydrogen and to obtain a linear signal/concentration relation for hydrogen it is necessary to use hydrogen as make-up gas for the TCD. A further improvement can be effected by installing an FID as a second detector. In this procedure only the permanent gases and methane are detected by the TCD; carbon monoxide and carbon dioxide are detected after passing through a methanizer to the FID, like the separated and backflushed hydrocarbons. The methanizer is a reactor that carries out reactions [I] and [II] in the presence of hydrogen and a suitable catalyst.

### Analysis with Capillary Columns

Capillary columns need a temperature program for maximum performance, which is why the main sphere of application is still the analytical laboratory. Process GCs are normally running under isothermal conditions because of the stability of retention times; nevertheless, more and more process GCs are equipped with capillary columns to benefit from the high resolution. A representative analysis

procedure is presented below (German Standard DIN 51872). By this method a large number of individual components in different kinds of gas fuels can be determined: permanent gases: helium, hydrogen, oxygen, nitrogen, carbon monoxide, carbon dioxide; hydrocarbons: methane, ethene, ethyne, ethane, propene, propane, *i*-butane, *n*-butane, 2,2-dimethylpropane, 2-methylbutane, *n*-pentane, cyclopentane, 2,2-dimethylbutane, 2,3-dimethylbutane, 3-methylpentane, *n*-hexane, benzene and cyclohexane, heptane, methylcyclohexane, toluene, octane, and higher hydrocarbons.

Three capillary columns are necessary. Two are connected in series in a two-column GC system (e.g. by Live-switching equipment as shown in **Figure 3**), and the third runs in a single-column system. After injection the gas sample passes through the first PLOT column, which contains porous polymer as the stationary phase. The  $\text{C}_2$ -hydrocarbons and carbon dioxide are separated, and the permanent gases including methane are flushed as sum peak to the second PLOT column containing molecular sieve. Here they are totally resolved. The higher hydrocarbons are removed from the first column by backflushing. The hydrocarbons eluting from the first column are detected by an FID. Carbon dioxide, which also elutes from this column, can be detected as methane after conversion in a methanizer. The components eluting from the molecular sieve column are detected by the TCD. If the TCD and

NV, needle valve; SV, solenoid valve; PR, pressure regulator; FR, flow restrictor;  $D_{mon}$ , monitor detector;  $D_{main}$ , main detector;  $P_1$ , inlet pressure;  $P_M$  mean pressure;  $\Delta_p$ , differential pressure; A, control line A; B, control line B.

methanizer/FID are connected, methane and carbon monoxide can also be detected by the FID.  $C_3$ - and higher hydrocarbons are separated in a WCOT-column with a very thick film of methyl-silicone as stationary phase and detected by an FID. A representative chromatogram is shown in **Figure 4**.

A double oven GC equipped with two or three detectors is an ideal instrument for this analysis because each column can work under optimal temperature conditions. In the two-column system argon is used as the carrier gas to give good sensitivity for helium and hydrogen. Carbon monoxide and carbon dioxide are detected by the FID. The TCD response is very poor because the thermal conductivities are similar to that of argon. The same analysis is possible using a single oven GC with only one FID. In this case very precise tuning of the chromatographic system is necessary to avoid simultaneous elution of peaks from two columns to one detector.

## Determination of Sulfur Compounds

The sulfur gases hydrogen sulfide, carbonyl sulfide, mercaptans, thiols, sulfides and tetrahydrothiophen,

can be determined using a separation column containing porous polymer as stationary phase and a sulfur-selective detector, such as an electrochemical, potentiometric or flame photometric detector. In spite of the selectivity, high concentrations of hydrocarbons may influence the signal. For this reason it is necessary to separate the sulfur compounds from the hydrocarbon matrix. This is possible for example using the heart-cut technique of the Live-switching system. Different methods are available based on temperature-programmed packed columns and capillary columns; packed columns are still very common but capillary columns are becoming more and more popular because of their high resolution capability and the lower tendency of the sulfur compounds to adsorb on the surface. Adsorption is a general problem in sulfur gas analysis and much work is devoted to avoiding or to reducing mistakes caused by this phenomenon.

## On-Site Analysis

Historically, high-quality gas analyses in fuels required sophisticated laboratory instrumentation. However, fast, portable, micro-gas chromatographs

**Figure 4** Flame ionization detector chromatogram a capillary column system with Live-switching equipment. (A) Separation by porous polymer column: 1, carbon dioxide; 2, ethene; 3, ethyne; 4, ethane. (B) Separation by molecular sieve column: 5, carbon monoxide. (C) Separation by WCOT column: 6, methane; 7, ethane (ethene, ethyne); 8, propene; 9, propane; 10, *i*-butane; 11, *n*-butane; 12, neopentane; 13, *i*-pentane; 14, *n*-pentane; 15, 2,2-dimethylbutane and cyclopentane; 16, 2,3-dimethylbutane; 17, 3-methylpentane; 18, *n*-hexane; 19, benzene; 20, cyclohexane; 21, *n*-heptane; 22, toluene; 23, *n*-octane; 24, xylene.

now allow the on-site analysis of complex gas streams, such as the natural gas used in gas turbines. This has the potential to save time and reduce costs. Typical sample throughput time is 1–3 min and hence, even with replicate injections, results are available within 10 min. Precision is often better than with laboratory methods due to the higher level of automation. Micro-gas chromatographs also have a wide linear dynamic range, typically from 10 ppm to 100% for many analytes.

### Introduction

In order to understand the chemistry of liquid fuels derived from oil (petroleum) it is first necessary to know a little about the crude oil from which these fuels originate. Petroleum is a highly variable, complex mixture of thousands of compounds. It can range from thin and watery to waxy solid, from brown to green to black, from ‘sweet’ low-sulfur oil to corrosive, foul-smelling ‘sour’ crude. Predominant among the compounds present are the hydrocarbons, compounds comprised solely of carbon and hydrogen. But a significant percentage of constituents in petroleum contain heteroatoms, most frequently sulfur and nitrogen. The amount and nature of these vary considerably with the type of petroleum; these will be mentioned specifically throughout this article where needed. The term ‘hydrocarbons’ is frequently used in the oil (and related) industry to refer to the compounds found in petroleum fractions whether heteroatomic compounds are present or not. Hydrocarbon fuels can also be obtained by refining non-petroleum crudes such as shale oil or liquid from tar, sand, or coal. Products derived from these materials, while important in a few localized markets and distinct in some ways, will not be included in the following discussion.

### Petroleum Refining

The compounds found in petroleum deposits cover a wide range of relative molecular mass, and the process of refining petroleum to produce usable fuels primarily serves to separate this complex mixture into narrower fractions (defined by boiling point, as described later) with properties suited to the end-use application. The lightest fraction is typically material that, while easily liquefied by pressure, is gaseous at ambient conditions. Called liquefied petroleum gas it will not be described in this section, but rather included in the discussion of gaseous fuels.

The next lightest fraction isolated at the refinery consists of the naphtha streams. These generally find their way into gasoline (petrol), either directly or after further treatment within the refinery to remove

impurities or to boost octane quality. Gasoline is comprised primarily of molecules containing four to 12 carbon atoms. Sulfur is the only significant heteroatom, and it is present as sulfide or mercaptan.

The gas oils are next, and they form the fuel for diesel engines. The carbon number is in the 10–20 range, and the sulfur level may be as high as 1 or 2% (m/m). In the gas oil boiling range sulfur compounds usually include thiophenes. Nitrogen and oxygen compounds are present in small amounts as well, and it is these polar compounds that give diesel fuel (gas oil) its color.

The heaviest fraction of petroleum that remains (the residuum or resid) may be treated in a number of ways, depending on the configuration of the particular refinery. Lubricant stocks may be distilled off under reduced pressure, and/or the residual material may be cracked to produce additional volume of lighter fuel components. The resid may be sold as heavy fuel oil, usually with the addition of a light ‘cutter’ stock (distillate) to improve handling, or it may be converted to petroleum coke for use as a solid fuel. The residual fraction contains virtually all of the organometallic compounds present in the starting crude. As these may determine the suitability of the residuum for further treatment or as a fuel, they are of significant analytical interest.

These products are discussed below in order of increasing boiling range (and thus carbon number), along with the analytical techniques used in their characterization. Most of the key properties that determine fuel performance are measured using physical parameters that often relate only indirectly to a particular fuel’s chemical composition. Since these physical properties comprise fuel specifications in virtually all industrialized countries, they are included in the discussion and the reader is referred to the appropriate standard-setting body for more details. Analytical testing generally serves to supplement the more routine characterization, and is typically needed to differentiate different batches of similar fuels.

### Gasoline (Petrol)

A fundamental and important property of gasoline is volatility. Volatility is described by vapor pressure and distillation, and these specifications may vary through the year and across geographical areas in order to match the volatility of the fuel to ambient conditions. Gasoline is typically used exclusively as a fuel for spark ignited internal combustion engines.

Since it is the fuel vapor that burns rather than the liquid, it is important that the fuel vaporizes easily. Ease of starting a cold engine depends primarily on the vapor pressure of the fuel. This is measured by the Reid vapour pressure (RVP) method and is primarily a function of the amount of butanes and pentanes present in the gasoline. At higher temperatures, as the engine is warming up, it is the mid-point of the distillation, the T50, which relates to smooth engine performance. Other distillation points, e.g., T10 and T90, may be controlled as well to ensure satisfactory vehicle operation. An elevated distillation endpoint may indicate contamination of the gasoline with heavier material. The distillation itself is performed using a procedure that, like all specification tests for petroleum products, is highly standardized by industry organizations such as the Institute of Petroleum and the American Society for Testing and Materials. These organizations should be consulted for details and further information on testing procedures discussed throughout this article. The distillation of petroleum products, while adequately repeatable, lacks the resolving power (theoretical plates) of fractional distillation, e.g., using a spinning band or packed distillation column. Nevertheless, it forms the basis for definition of the boiling range of the various petroleum products, as listed in Table 1.

A second key measure of a gasoline's performance is octane rating. As the gasoline vapor-air mixture is compressed within the cylinder by the rising piston, it heats up (from compression as well as by absorbing heat from the engine surfaces). If it gets hot enough it will spontaneously ignite. In a normally operating, spark-ignited engine the fuel burns as a result of the spark plug igniting the mixture. Spontaneous ignition ahead of the normal flame causes a metallic rapping noise called knock. Such abnormal combustion generates much higher than normal pressure within the cylinder and, in severe cases, can damage the engine. Octane rating is nothing more than an expression of a particular fuel's ability to withstand the tendency to

preignite. It is measured in a laboratory engine that has a movable cylinder, and thus variable compression ratio. A test fuel is bracketed by reference fuels of known octane values and the knock intensity is compared to determine the octane rating of the sample. Octane rating is one of the key parameters in determining the value and use of refinery streams.

Until the last few years, most gasoline contained organolead compounds to improve the fuel's octane rating. These antiknock additives are typically mixtures of tetramethyl lead, tetraethyl lead, and the mixed analogs thereof. While these components are highly toxic in neat form, their low cost and high effectiveness made them the additive of choice for boosting octane ratings. They can be determined individually by gas chromatography (GC) using a lead-selective detector (atomic absorption or emission). More commonly, however, total lead is determined by X-ray fluorescence and the results are expressed as tetraethyl lead equivalent.

As lead compounds are being phased down to reduce environmental lead pollution, other compounds are being called upon to replace the lost octane value. Aromatics have the highest octane ratings of naturally occurring petroleum constituents, and their use has increased significantly in recent years. They can be determined in gasoline by a number of techniques. The most widely used is the fluorescent indicator adsorption (FIA) technique. A desorption (dry column) separation is carried out on a long, slender silica gel column and the hydrocarbon types (saturates or paraffins followed by olefins followed by aromatics) are quantified by measuring the length of the column wetted by each. A mixture of fluorescent dyes is added to enable detection.

The method is rapid and fairly simple, but subject to variation in the quality of the silica gel employed. The lightest components in gasoline need to be removed from each sample in order to obtain the best results, and certain compound types can elute with the wrong group, for example, cyclic di-olefins elute with the aromatics. The method gives results in

**Table 1** Typical properties of some representative refined products

Product	Principal application	Boiling range (°C)	Vapor pressure <sup>a</sup>	Yield per barrel <sup>b</sup> (%)

<sup>a</sup> Reid vapor pressure.

<sup>b</sup> Average figures. May vary considerably for any particular refinery.

liquid volume per cent. Mass spectrometry can be used to determine aromatics in gasoline, giving information about what types of aromatic ring (benzene, indane, naphthalene) are present in addition to total aromatic content in weight per cent. GC with an aromatic selective detector (photoionization, mass spectrometer) can also be used once reasonable correction is made for detector response. A universal GC detector can be used with very high resolution columns, although this is the most tedious approach, requiring complete separation of the sample and extensive calibration. Alternatively, a polar column will retain aromatics for elution after the bulk of the paraffins. In this manner benzene can be made to elute after *n*-decane.

In addition to the octane available from the refinery streams, many gasoline blenders today rely on oxygenated compounds for providing the required octane rating. The lower relative molecular mass alcohols have high blending octane values and have been widely used. As a group they tend to degrade the gasoline's tolerance for water. Once the solubility limit is exceeded the alcohol can separate from the gasoline, with the resulting water-alcohol mixture being fed to the engine. Stalling or inability to start can result. Also, being small molecules, methanol and ethanol raise the RVP of the gasoline-alcohol blend. This is undesirable from an environmental viewpoint. Alcohols also have a higher latent heat of vaporization than hydrocarbons, and this can adversely affect the warming up performance of the engine. The other class of gasoline oxygenates is ethers. By far the most common is methyl tertiary-butyl ether. This is much more like gasoline in its water tolerance and vapor pressure behavior, which accounts for its widespread acceptance by the industry. Other ethers can be expected to emerge as oxygenates become more important contributors to the gasoline pool, e.g., ethyl tertiary-butyl ether and tertiary-amyl methyl ether. All these oxygenates can be determined using GC. A multiple column arrangement employing switching valves is the preferred technique. Use of an oxygen-selective detector such as the atomic emission or oxygen-flame ionization detector provides another option. An alternative approach, particularly for rapid screening of samples, is to use mid-infrared (IR) spectroscopy. A number of instruments are commercially available with preprogrammed calibrations for the common oxygenates.

Sulfur is generally present in gasoline at levels up to 0.3% (m/m). The preferred technique for sulfur determination is X-ray fluorescence, although other procedures may be employed. The X-ray procedure is rapid, sensitive down to  $10 \text{ mg kg}^{-1}$ , and calibration is straightforward. The sulfur K-alpha line at

53.73 nm is used, and no sample preparation is needed. Alternatively, the sample may be combusted and the sulfur oxidized to sulfate, which is then determined gravimetrically. While tedious, the technique does not require sophisticated instrumentation. The method is potentially less sensitive than X-ray fluorescence, and high aromatic levels can cause smoke during the combustion step, necessitating sample dilution. For trace sulfur levels (below  $100 \text{ mg kg}^{-1}$ ) oxidative microcoulometry may be used. Within the past few years governments have begun to introduce legislation that will have the effect of reducing the amount of sulfur in gasoline to less than 30 ppm. Most governments intend to reach this goal by 2005. At these reduced levels of sulfur content X-ray fluorescence is still a satisfactory method of sulfur analysis, but less costly and quicker analytical methods based on ultraviolet (UV) fluorescence are also standard.

Occasionally, it is important to characterize a gasoline (or a refinery stream used to blend gasoline) more completely than the typical properties described above. Examples might be: calculating physical properties from the individual components present, correlating the fuel composition with unburned hydrocarbons present in the engine exhaust, or predicting petrochemical end products from refinery conversion processes. In most cases GC is the technique of choice. The volatility and thermal stability of the hydrocarbons facilitate vapor-phase analysis, while few other techniques possess the resolving power needed to separate the hundreds of components found in a typical gasoline. As such, the modern petroleum research laboratory will be well equipped with GC instrumentation. Long, nonpolar capillary columns serve most purposes adequately, and provide a separation based primarily on boiling point. To accommodate the wide boiling range of most products, extensive use is made of temperature programming. **Figure 1** illustrates a number of different fuel products separated by GC according to boiling point. Notice how resolution of the individual components is lost in the heavier products. Selective detectors may be used to decrease interference from saturated hydrocarbons when functionalized or heteroatomic (generally sulfur) species are the target.

In many cases analysis by GC involves quite significant peak calibration and identification, only to be followed by extensive peak summing and averaging. Thus, GC is not the technique of choice for such tasks as predicting octane numbers. More often, spectroscopic techniques are correlated through sophisticated statistical treatment known broadly as chemometrics. Applications of near- and mid-IR

**Figure 1** Gas chromatographic separation by boiling point (solute volatility) of various fuel products: gasoline (bottom), kerosene (middle), diesel fuel (top). Note that heavier (higher boiling range) products elute at greater retention time. Prominent components are seen as discrete peaks while a complex mixture of unresolved isomers yields an elevated baseline.

spectroscopy as well as nuclear magnetic resonance spectroscopy are being established, which can outperform traditional testing methods. This can be expected to become more important in online process control, where the real-time results can be used to improve product quality and reduce follow-up specification testing.

## Diesel Fuel (Gas Oil)

Fuel for diesel engines is different from gasoline in several important respects. While gasoline is introduced to the combustion chamber of the engine as a

premixed fuel–air charge to be ignited by the spark plug, diesel fuel is injected into the hot, compressed air at roughly the time the piston is at the top of its stroke. With the exception of cold starting in those vehicles equipped with a glow plug, it is the heat of this compressed air that ignites the fuel. Vaporization, fuel–air mixing, and combustion all take place simultaneously. In contrast to gasoline, where the fuel's ability to resist ignition by heat alone (as indicated by octane number) is desired, the best diesel fuels ignite readily after injection. The term used to describe this is cetane number and, like octane number, it is determined in a special laboratory engine. Octane and cetane ratings are inversely related. Aromatic hydrocarbons have a high octane but a low cetane number. Straight chain paraffins are just the opposite. In addition to engine determination, cetane rating can be estimated using chemometrics or by a formula using density and distillation values. This latter procedure gives a value known as the cetane index.

Having a higher relative molecular mass than gasoline, diesel fuel can present a problem in cold weather. Straight chain paraffins, desirable from a cetane rating viewpoint, can precipitate at low temperature as wax crystals. These can plug fuel filters, starving the engine of fuel. They can also interlock in a rigid lattice causing the entire fuel volume to solidify. The temperature at which this occurs is called the pour point. Additives are often used which prevent the formation of the rigid lattice (but not the wax crystals themselves); these are called pour point depressants. They are typically ethylene–vinyl acetate copolymers, and can be determined using IR spectroscopy. Another low-temperature property is the cloud point. This is the temperature at which the first wax crystals can be seen forming. Somewhere between the cloud and pour points there is usually enough wax to plug a vehicle filter. Several test rigs have been developed to determine low-temperature operability of diesel fuels: cold filter plugging point, low temperature flow test, and so on. No test can completely predict field performance, as each vehicle has design features that affect its response to fuel wax.

The sulfur present in diesel fuel depends primarily on the nature of the crude from which it was refined and how extensively it was treated during the refining process. High sulfur crude, of course, yield higher sulfur distillate products. Cracking of heavy material will likewise tend to contribute to higher sulfur levels in the middle distillates, as the heavier portion of the crude contains proportionally more sulfur. Hydrotreating, the refining process by which hydrogen is added to the fuel and sulfur (or nitrogen) is removed, can be used to a greater or lesser degree

depending on the specifications of the desired end product. Sulfur content is a concern to the end user as a portion of the sulfur is converted to sulfuric acid in the crankcase lubricant (engine oil). Engine oils contain detergent and other material that neutralize this acid, but a low sulfur fuel places less stress on the lubricant and can lead to longer engine life. Additionally, a portion of the sulfur is converted to sulfate in the exhaust gas, which contributes to exhaust particulate levels. Since particulates are one of the regulated pollutants for diesel engines, newer low-emission engines require low sulfur fuel, typically 0.05% (m/m). Judicious crude selection combined with hydrotreating is used to produce such fuel.

Sulfur in middle distillates is determined using much the same methodology as for gasoline. X-ray fluorescence is the technique of choice. For best results standards should be prepared in a matrix that matches the sample type. A variety of combustion-based approaches are also available, though their applicability to low sulfur distillates may be limited owing to poor sensitivity.

Most middle distillate fuels tend to be comprised primarily of straight run distillate streams, as opposed to cracked stocks. Olefinic unsaturation is thus low. Aromatics, however, are most often in the 20–50% (v/v) range. Being dense, aromatics possess high-energy density measured in British thermal units per unit volume. This is an advantage to the consumer. However, aromatics also have an inherently low cetane value, a distinct disadvantage, particularly for ease of starting a cold engine. More recently, aromatics have been implicated as contributing to the generation of nitrogen oxides ( $\text{NO}_x$ ) in diesel engines. Surprisingly, only California has enacted legislation limiting the amount of aromatics allowed in diesel fuel, although most other western legislatures have stated their intention to follow suit. Since 1993, all diesel fuel sold for on-road use in California has been restricted to no more than 10% (v/v) aromatics. This level is far below current US averages, and one that requires extensive hydrotreating to reach. Given the investment required for the high-pressure processing units involved, some refiners have opted to abandon this market rather than comply. This establishes a new landmark in the role of base fuel parameters in diesel fuel marketing. Historically, diesel fuel has been bought and sold as a commodity with little attention to its composition.

As with gasoline, aromatics are most frequently determined using the FIA test, although this method was not designed for middle distillates (these cause slow development of the separation with attendant large variability). Nevertheless, it is readily available in most petroleum laboratories and has been widely

used. A newly developed technique is emerging that offers an alternative to FIA for aromatics determination. Supercritical fluid chromatography (SFC) is a hybrid of gas and liquid chromatography that uses high-pressure carbon dioxide to separate the fuel into hydrocarbon classes. Aromatics are eluted as a class (as in liquid chromatography) and detected with a flame ionization detector (as in GC). The method is more rapid than FIA and offers better precision as well. Mass spectrometry can be used to characterize the types of aromatics present. GC by itself is not as useful as for gasoline; the individual components are not well resolved making identification and calibration difficult. Analysis by liquid chromatography most often employs UV absorbance detection. This requires careful calibration before total aromatics can be measured. The separation is easily achieved using normal phase (silica) columns, however.

Other parameters of importance in diesel fuels are physical properties. Viscosity of these fuels is higher than gasoline, and influences the injection of the fuel into the combustion chamber. Lubricity, a somewhat related property, is a concern since the fuel also serves to lubricate the moving parts of the fuel pump and injectors. Inadequate lubricity can lead to scoring and wear. This is currently a subject of debate, as the naturally occurring sulfur compounds are thought to provide the film needed to keep highly loaded metal parts from coming into direct contact. The move to lower sulfur levels threatens to allow more pump wear.

## **Turbine Fuels**

Fuels for turbine engines are a special class of distillate fuels. By far the most common turbine engines are those of jet aircraft. Other applications can be found in power plants and aboard ships. These engines require a clean burning, economical fuel. Light distillate (kerosene) is almost exclusively used, and there can be much exchange and rebranding of products between aviation turbine fuel, light diesel fuel (typically used during cold weather and for two-cycle urban bus operation), and other distillate markets. The turbine blades are of special metallurgy, so residual material that could contain vanadium is to be avoided at all costs. Apart from special cleanliness and fuel handling considerations for aircraft fuel, analytical considerations of turbine fuel are the same as for other distillates.

## **Residual Fuels**

The heavy material that remains after refinery processing to remove the lighter material is frequently

sold as a fuel. Since it is essentially nonvolatile it is unsuitable for use in spark-ignited engines. It may be used in boilers, in which case it is pumped (sprayed) in continuously. Boiler fuel application is rather tolerant of fuel properties, with sulfur content and viscosity being the prime criteria. Stationary boilers, e.g., power plants, may be fitted with scrubbing equipment to remove sulfur gases from the stack gas. Pour point and viscosity of residual fuel is typically very high, with some fuels being a solid at ambient temperature. External heat may need to be supplied to keep the fuel sufficiently fluid for handling.

Alternatively, the residue may serve as fuel for medium- and low-speed diesel engines. These large engines are typically found in vessels and electric generating plants. In this application the fuel is injected intermittently to coincide with the start of the power stroke of the engine cycle. Straight resid (called bunker fuel) is often too heavy or viscous for optimum operation in these engines, so most fuel is blended with a distillate stock to a viscosity specification. One potential problem arising from the addition of such cutter stocks is the precipitation of asphaltenes. Several spot and screening tests have been developed to identify heavy fraction-cutter combinations that produce unstable fuel. Unfortunately, two stable fuels can become unstable when mixed together, depending on their asphaltene and solubility characteristics. The problem is most pronounced for vessel operation, where fuel may be obtained at ports located throughout the world and segregation of the fuel batches is not feasible. Instability leads to greater sludge burden on shipboard fuel handling systems (centrifuges, filters, and homogenizers). As these large engines are either kept running continually or are started with a lighter, distillate fuel, cold starting is generally not a major concern. As such, residual fuel is not routinely rated for ignition quality (cetane number). The distillate cutter stock typically provides for adequate auto-ignition of the fuel.

The trace elements present in the original crude are also concentrated in the residue, giving rise to several concerns. Residual fuel sulfur level is the highest of all oil-based fuels, and can be 3–5% (m/m). This has a direct effect on the acid loading of the crankcase oil, as discussed previously, and marine diesel lubricants often have very high alkalinity to control wear and corrosion. Vanadium is a common trace metal in petroleum, and its presence in the fuel can cause problems due to the formation of corrosive combustion products such as sodium vanadate and vanadium pentoxide. Vanadium is typically determined by ashing the sample followed by digestion of the residue in acid and quantification by atomic absorption or emission. Sodium also can contribute to corrosive attack; it may enter the fuel through contamination with seawater. It can often be determined at the same time as vanadium. Aluminum is a metal of concern in heavy fuel, as it indicates the presence of catalyst fines from refinery cracking operations. It is the abrasive nature of these small (less than 0.02 mm) particles that is the problem. Different catalysts contain widely different amounts of aluminum, so this is an imprecise as well as indirect measure of catalyst fines. Aluminum is determined in much the same way as vanadium, except that the ash is fluxed with lithium tetraborate prior to acid dissolution.

## Performance Additives

Gasoline and diesel fuel often contain additives to improve engine performance. Some examples of these are shown in Table 2. The most important class of performance additives is detergents/dispersants. While these perform the indicated task of minimizing engine deposits, they also serve as the primary means by which marketers differentiate their products. Very often products are distributed and exchanged as commodities between the point of

**Table 2** Some common gasoline additives

<i>Description</i>	<i>Function</i>	<i>Composition (typical)</i>
Antiknock	Boost octane value	Tetraalkyl lead, methyl cyclopentadienyl manganese tricarbonyl
Antioxidant	Minimize gum (residue)	Aromatic diamines, hindered alkyl phenol
Metal deactivator	Chelate trace metals	<i>N,N'</i> -Disalicylidene-1,2-propanediamine
Dye	Visual identification	Anthraquinones, azo compounds
Corrosion inhibitor	Prevent rust	Organic acids and salts
Detergent	Keep carburetor and injectors clean	Alkyl amines, amine phosphates
Dispersant	Keep entire intake system <sup>a</sup> clean	Polymeric <sup>b</sup> amines and succinimides
Dehazer	Coalesce suspended water droplets	Ethoxylated/propoxylated surfactants
Biocide	Prevent biological growth in storage tanks	Quaternary ammonium salts, boron compounds

<sup>a</sup> Carburetor, injectors, and intake valves.

<sup>b</sup> Poly(isobutenyl) or poly(butoxy).

manufacture and final sale to the consumer. As a result, the properties of the base fuel may be the same across several marketers. Addition of additives at the fuel terminal thus provides a simple and effective means of adding value to the product. A high-performance additive package can confer a competitive advantage upon a particular marketer; therefore, composition of these materials is often a closely kept secret.

Owing to their chemical dissimilarity to the matrix, the low dose at which they are used, and their strategic importance for brand identification, additives present one of the best opportunities for sophisticated analysis in the oil industry. When the analyst knows the chemical nature of the target compound, e.g., when he/she is developing a method to monitor an additive, the technique of choice may be obvious. When he/she is seeking to detect or identify an unknown material, as in a competitor's fuel, the situation is more difficult. In either case one will most likely want to remove the bulk of the gasoline, generally by evaporation. In fact, in some cases the weight of the residue after evaporation (the gum value) may be sufficient to indicate the presence of an additive. More likely spectral techniques can be applied to the residue to locate characteristic functional group absorbances. The polymeric backbone of most additives generally covers a range of relative molecular mass. This limits the usefulness of mass spectrometry, which otherwise would be valuable owing to the high sensitivity afforded by that tool. More often than not it is IR spectroscopy that provides the greatest amount of information on performance additives.

Separation of the evaporation residue by liquid chromatography provides fractions for subsequent analysis that are typically less complex than the whole residue. A typical scheme might employ silica gel or a similar polar adsorbent in a 10–20 mm diameter column. Elution of the sample with solvents of increasing strength thus serves to separate nonpolar components (mineral oil or hydrocarbon polymers such as polyisobutylene) from more highly functionalized components of the additive package. The range of relative molecular mass of many common additive classes makes their collection in a single fraction difficult, and trial and error is often needed to achieve the best separation. There is no standard practice for such analysis, and there is considerable 'art' involved. As with many techniques,

experience is the best teacher, and each laboratory probably has a preferred way of doing things, along with a library of spectra from previous work. Nevertheless, there is abundant opportunity for novel application of instrumental and microscale techniques, e.g., gel permeation and SFC followed by nuclear magnetic resonance spectroscopy or mass spectrometry. Finally, aspiring analysts should remember that additives, being commercial products, are rarely as simple as the patent or synthetic pathway would suggest. By-products are common, and these are often of higher relative molecular mass, e.g., dimers or further reaction products. The presence of these materials in minor amounts can often complicate an interpretation and skew calibration factors.

Additives in diesel fuel are generally similar to gasoline, being nitrogenous, hydrocarbon-soluble detergents and dispersants. The less volatile nature of the matrix can complicate the concentration step, but otherwise the general approach is similar to that for gasoline additives.

## Introduction

For functional group analysis, chemical reactions that are selective and specific to the analytes have been utilized. The products obtained after the reactions have properties that are desirable (sensitive and selective) for analysis. The reagents used for functional group analysis are required to have the two structural features: (1) a reactive moiety towards the target functional group; (2) a signaling moiety with a high detector response. To date, many reagents used for functional group analysis have been developed and used in combination with analytical instruments (e.g., gas chromatography, GC; liquid chromatography, LC; capillary electrophoresis, CE, etc.).

In this article, the representative analytical methods for several functional groups such as amino, hydroxy, aldehyde and ketone, carboxyl, thiol, and halogen groups are described as well as their application.

## Amino Group

Amines such as amino acids, polyamines, catecholamines, and peptides exist in most of the biological samples. In general, amino groups are so reactive that chemical reactions with the analytical reagents proceed under fairly mild conditions, and the numerous reagents for amines have been developed and applied to the highly sensitive determination of a large variety of analytes.

Primary amines and amino acids selectively react with carbonyl compounds such as benzaldehyde, furfural, and pentafluorobenzaldehyde in aqueous medium at room temperature, and give Schiff's bases in good yields. This reaction is used for the determination of aliphatic diamines and aromatic amines by GC with a flame photometric detector or an electron capture detector. However, a cleanup step for sample preparation is required to remove the excess reagent.

*o*-Phthalaldehyde (OPA) in the presence of certain reducing reagents, such as 2-mercaptoethanol or 3-mercaptopropionic acid, reacts with primary amines and amino acids to form highly fluorescent isoindole derivatives at room temperature. The detection limits for amino acids by an LC-ultra violet (UV) detection

method are  $\sim 1$  pmol on-column at a signal-to-noise (S/N) ratio of 3. The reaction of OPA using a chiral thiol compound such as *N*-acetyl-L-cysteine as a reducing agent is important for the separation of chiral amines, especially amino acid enantiomers. OPA is to be applied to both pre- and postcolumn LC, because OPA itself is nonfluorescent. The resultant isoindole derivatives are also electroactive, and thus nanogram levels of amino acids can be determined with an electrochemical detector (ECD). Moreover, after postcolumn derivatization with OPA and 2-mercaptopropionic acid, primary amino acids are determined by liquid chromatography (LC)-electrospray ionization (ESI)-mass spectrometry (MS). The detection limits (20–250 fmol) are 100 times higher than those with a direct determination of amino acids by LC-ESI-MS. OPA derivatives of amino acids are rapidly separated by capillary zone electrophoresis (CZE) or micellar electrokinetic capillary electrophoresis (MEKC) and sensitively detected by laser-induced fluorescence (LIF) detection. 2,3-Naphthalenedialdehyde (NDA), an OPA analog, reacts with primary amines in the presence of cyanide ion to produce highly fluorescent cyanobenz[*f*]isoindole (CBI) derivatives. The CBI derivatives have also been found to be electroactive. The detection limits of CBI derivatives of amino acids with Fluorescence (FL) and ECD are 15–30 and 100 fmol, respectively. After derivatization with NDA, the amphetamine related compounds are determined by LC-peroxyoxalate chemiluminescence (PO-CL) detection with the detection limit of 0.2 fmol. OPA analogs, NDA and 3-(2-furoyl)quinoline-2-carbaldehyde (FQCA), are shown in **Figure 1**.

Fluorescamine under the alkaline conditions rapidly reacts with primary amines and amino acids to give fluorescent derivatives at room temperature. The advantageous features of this reaction are as follows: (1) fluorescamine is nonfluorescent; (2) fluorescamine can be hydrolyzed to the nonfluorescent product; (3) the reaction with secondary amines can form nonfluorescent derivatives, which allows selectivity to primary amines. For those reasons, fluorescamine can be applied to pre- and postcolumn derivatization of primary amino compounds with LC-FL or CZE-LIF detection.

2,4-Dinitrofluorobenzene is utilized for the analysis of primary and secondary amines and amino acids. The derivatives are determined by measuring absorbance at 330–360 nm. *N,N*-diethyl-2,4-dinitro-5-fluoroaniline is used in a similar manner and

applied to the LC–UV detection of these compounds. A precolumn derivatization with 2,4-dinitrofluorobenzene is adopted to improve the detection properties of amino alcohols and amino acids in LC–ECD. The dinitrophenyl group of the derivatives is appropriate for ECDs operated in the reduction mode.

Isocyanates and isothiocyanates react with primary and secondary amines to form urea and thiourea

**Figure 1** The reaction scheme for primary amine with OPA and OPA analogs.

derivatives (**Figure 2**). Phenyl isothiocyanate (PITC) and naphthyl isothiocyanate are reported to be used as reagents for spectrophotometric detection. 2,3,4,6-Tetra-*O*-acetyl- $\beta$ -D-glucopyranosyl isothiocyanate (GITC) is used for enantioselective analysis of amino acid. These reagents can be applied to the precolumn derivatization of a variety of amines in LC and CE. PITC, as one of the Edman reagents, has been used for the sequential analysis of *N*-terminal amino acid. Usually, the derivatives are once cyclized and rearranged under the acidic condition to form 3-phenyl-2-thiohydantoin derivatives. The derivatives separated are detected at 254 nm by LC. Similarly, fluorescein isothiocyanate (FITC), 4-(*S'*,6'-dimethoxybenzothiazolyl)phenyl isothiocyanate (BHBT-NCS), 4-(2-cyanoisindolyl)phenyl isothiocyanate (CIPITC), and 5-isothiocyanato-1,3-dioxo-2-*p*-tolyl-2,3-dihydro-1*H*-benzo[*d,e*]isoquinoline (DTDITC) have been developed and applied to LC–FL methods (**Figure 2**).

Luminol derivatives, 4-isothiocyanatophthalhydrazide and 6-isothiocyanobenzo[*g*]phthalazine-1,4-(2*H*,3*H*)-dione (IPO) are synthesized as highly sensitive chemiluminescent reagents (**Figure 2**). Reactions with

**Figure 2** The reaction scheme for primary amine with PITC and analytical reagents containing isothiocyanate group.

primary and secondary amines proceed at 80°C for 10 min in the presence of triethylamine as a catalyst. The detection limits for primary and secondary amines are in the range of 30–120 and 0.8–3 fmol on-column ( $S/N = 3$ ), respectively. *p*-*N,N*-Dimethylaminophenylisothiocyanate (DMAPI) reacts with amino acids to give phenylhydantoin derivatives. After oxidation at pH 2, the derivatives are determined by LC–ECD with the detection limits of 0.5–1.0 ng.

The analytical reagents having sulfonyl chloride as a functional group can react with secondary and primary amines and amino acids under the weak alkaline condition to form sulfonamide derivatives. 1-Dimethylaminonaphthalene-5-sulfonyl chloride (DNS-Cl), 4-*N,N*-dimethylaminoazobenzene-4'-sulfonyl chloride (Dabsyl-Cl), 4-(*N*-phthalimidyl)benzenesulfonyl chloride (Phisyl-Cl), and 2-(5',6'-dimethoxybenzothiazolyl)benzenesulfonyl chloride (BHBT-SOCl) react in a similar manner and can be applied to the LC–FL or CE–LIF method (Figure 3). As these reagents and their hydrolyzates are fluorescent, they should be used as precolumn reagents. The analyses of amines and amino acids with DNS-Cl

have been widely performed in combination with various instruments. For example, DNS-amino acids are separated by CZE followed by detection of absorbance at 254 nm. Although DNS-amino acids are fluorescent by nature, an aqueous condition in CE results in a marked decrease of their quantum yields. A highly sensitive determination of DNS-amino acids with detection limit at the subfemtomole level is achieved by LC–PO–CL with a microbore column.

An acyl chloride such as benzoyl chloride can react with secondary and primary amines and amino acids to form *N*-substituted benzamide derivatives. Analytical reagents used for precolumn derivatizations are *p*-nitrobenzene azobenzoyl chloride for LC–UV, *o*-acetylsalicyloyl chloride for LC–ECD, and 3,4-dihydro-6,7-dimethoxy-4-methyl-3-oxoquinoxaline-2-carbonyl chloride (DMEQ–COCl) and 4-(4,5-diphenyl-1*H*-imidazol-2-yl)benzoyl chloride (DIB-Cl) for LC–FL, respectively. Pentafluorobenzoyl chloride (PFBC) is used as an acylating reagent for GC with electron-capture detection (Figure 4). Many of those described above can also react with hydroxyl and phenol groups.

The analytical reagents having an *N*-succinimidyl group as a reactive functional group can easily react with primary and secondary amines. 6-Aminoquinolyl-*N*-hydroxysuccinimidylcarbamate (AQC) can rapidly react with amines to form stable fluorescence derivatives. *N*-Succinimidyl-1-naphthylcarbamate (SINC) and *N*-succinimidyl-1-fluorenylcarbamate (SIPC) immediately react with analytes in a few seconds, and thus are suitable for LC–FL with an automated precolumn derivatization after removing the excess reagent by hydrolysis. Luminarin 1, having quinolizino coumarin structure, is used for precolumn labeling of amino acids in LC–PO–CL, and the labeled compounds can be detected as low as ~100 fmol on-column. *N*-(4-Aminobutyl)-*N*-ethylisoluminol (ABEI) is known as a chemiluminescent reagent for amines. The derivatization of amines with ABEI is performed as follows: initially, ABEI reacts with *N,N'*-disuccinimidyl carbonate (DSC) to form the intermediate, ABEI–DSC, which reacts with amines to give the final derivatives in the presence of triethylamine as a catalyst. The succinimidyl types of analytical reagents are shown in Figure 5.

Halogenobenzofurazans such as 4-fluoro-7-nitro-2,1,3-benzoxadiazole (NBD-F) and 4-chloro-7-nitro-2,1,3-benzoxadiazole (NBD-Cl) work on amines rapidly under alkaline conditions. As the hydrolyzed products of these reagents also fluoresce intensely, they are used only for precolumn derivatization. 4-(*N,N*-Dimethylaminosulfonyl)-7-fluoro-2,1,3-benzoxadiazole (DBD-F) is a similar sensitive reagent

**Figure 3** The reaction scheme for DNS-Cl with amine and analytical reagents containing sulfonyl chloride group.

**Figure 4** Analytical reagents with acyl chloride for amines.

to NBD-F. DBD-labeled amino acids were separated on a reversed phase column and detected at femtomole levels by PO-CL (**Figure 6**). Halogenobenzofurazans can also react with hydroxyl and phenolic moieties.

Acyl amides (**Figure 7**) such as *N,O*-bis(trimethylsilyl)acetamide (BSA) and *N,O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA) have been used as silylating reagents for GC. Amino compounds can be converted to silyl derivatives to increase volatility. The reactivity of these reagents to primary amine is higher than that of secondary amine. On the other hand, *N*-methyl bis(trifluoroacetamide) (MBTFA) has been used as an acylating reagent. This reagent is very volatile and the by-product accompanied, *N*-methyltrifluoroacetamide, does not cause column damage. The reagent reacts not only with amines, but also with alcohols, phenols, and thiols.

Chloroformates are useful analytical reagents for primary, secondary, and tertiary amines. The reaction of these reagents with amines can be performed easily, and the resultant carbamate derivatives are suitable for GC analysis. The carbamate derivatives obtained from primary and secondary amines are determined selectively and sensitively by GC-MS and -ECD. After dealkylation, tertiary amines are derivatized to carbamates in the same manner for primary and secondary amines. The carbamate derivatives obtained with pentafluorobenzyl chloroformate are determined with high sensitivity by GC-ECD. Chloroformates also react with phenols, thiols, imidazoles, as well as amines.

Fluorenylmethyl chloroformate and its analogs (2-naphthyl chloroformate (NT-COCl), 9-fluorenylmethyl chloroformate (FMOC-Cl), and 2-(1-pyrenyl)ethyl chloroformate (PE-COCl)) are used as precolumn derivatization reagents for HPLC.

**Figure 5** Succinimidyl analytical reagents for amines.

Tris(2,2'-bipyridyl)ruthenium(II) ( $\text{Ru}(\text{byp})_3^{2+}$ ) is used as the electrogenerated CL (ECL) reagent for the amino compounds in the LC-CL detection system. The CL reaction is supposed to proceed as follows: initially, the oxidation of  $\text{Ru}(\text{byp})_3^{2+}$  to  $\text{Ru}(\text{byp})_3^{3+}$  is performed at the electrode surface, and then  $\text{Ru}(\text{byp})_3^{3+}$  reacts with amines to emit light at 620 nm. The ECL intensity is proportional to the amount of amines, and the order of increasing CL intensities is tertiary > secondary > primary amines. Dansyl derivatization of primary, secondary, and tertiary amines are used to increase the sensitivity. DNS-Glu can be determined by ECL with the detection limit of 2 pmol.

## Hydroxy Group

Hydroxy compounds such as alcohols, carbohydrates, steroids, and phenols are known to play important physiological roles. Although many analytical reagents have been developed for determination of hydroxy compounds, some of them can be also applied to amines as described in the previous section (e.g., isocyanates, sulfonyl chlorides, acyl chlorides, halogenobenzofurazans, acyl amides, and chloroformates). The derivatization conditions for hydroxy compounds are relatively more drastic than those for amines. By using fairly different conditions from those for amino compounds,

**Figure 6** Reaction scheme for halogenobenzofurazan and its analogs.

**Figure 7** Acyl amide reagents for amines.

selective analyses for hydroxy compounds can be achieved.

Carbonyl azides react with alcoholic hydroxy compounds to form the corresponding urethanes. In the same manner, ferrocenoyl azide, and 3-ferrocenylpropionyl azide can be derivatized, hydroxysteroids and the resultant derivatives are determined electrochemically by LC with the detection limits at subpicomole levels. 2-[2-(Azidocarbonyl)ethyl]-3-methyl-1,4-naphthoquinone (AMQ) reacts with primary and secondary alcohols to produce carbamic acid derivatives and is used in LC with ECD and FL detections. 7-Methoxycoumarin-4-carbonyl azide (7-MC-4-CON<sub>3</sub>) and 3,4-dihydro-6,7-dimethoxy-4-methyl-3-oxoquinoline-2-carbonyl azide (DMEQ-CON<sub>3</sub>) are also applied to LC with FL detection as precolumn reagents.

The reaction of carbonyl nitrites with primary or secondary alcohols in the presence of basic catalyst is

utilized for the analysis of alcohols. 1-Anthrionitrile (1-AN), pyrene-1-carbonylnitrile (PCN), and 4-dimethylamino-1-naphthoylnitrile (DNN) have been reported on their applications in LC-FL analysis.

Phenols react with 4-aminoantipyrine to give indophenols in the presence of hydrogen peroxide and peroxidase under weak alkaline conditions. The resultant indophenols are determined by absorptiometry. Potassium hexacyanoferrate (III) can also be used as an oxidant. As the indophenols have electrochemical activity, this reaction is utilized for precolumn derivatization for LC-ECD.

## Aldehyde and Ketone Groups

Compounds containing aldehyde and ketone groups in their molecules are major constituents of food aromas, and are widely distributed in the environment. Especially carbonyl compounds in the air are considered to exhibit toxicity.

In this reaction, hydrazones are efficiently formed between carbonyl compounds and hydrazino compounds under acidic conditions (Figure 8). For instance, 2,4-dinitrophenyl hydrazine is used as a colorimetric reagent for carbonyl compounds. Hydrazone produced from the reaction of 2,5-dihydroxybenzohydrazide (DBH) with dehydroepiandrosterone can be electrochemically detected at a low oxidative potential with detection limit at subpicomole levels. 5-*N,N'*-Dimethylaminonaphthalene-1-sulfonylhydrazide (DNS-H), 4-hydrazino-7-nitro-2,1,3-benzoxadiazole (NBD-H), 4-(*N,N*-dimethylaminosulfonyl)-7-hydrazino-2,1,3-benzoxadiazole (DBD-H), 1*H*,5*H*,11*H*-[1]benzopyrano[6,7,8-*ij*]quinolizine-9-acetic acid, 2,3,6,7-tetrahydro-11-oxohydrazide (Luminarin 3), and 4-(2-phthalimidyl)-benzohydrazide (PBH) are used as fluorescence labeling reagents and have been successfully applied to LC determination of carbonyl compounds in biological samples.

DNS-H can be used in combination with PO-CL, and its application study on the determination of oxo-steroids and oxo-bile acid ethyl ether by LC has been reported. The detection limits for hydrazone derivatives are at a level of a few femtomoles.

## Carboxy Group

There are many pharmaceutical preparations and biological compounds containing carboxylic group, i.e., fatty acids, prostaglandins, steroids, bile acids,  $\alpha$ -keto acids, and glucuronic acid. These compounds play important physiological roles to achieve homeostasis.

**Figure 8** Analytical reagents with hydrazine for aldehyde and ketones.

**Figure 9** Reaction scheme for NPH with carboxylic acid and hydrazine analytical reagents.

Hydrazino compounds can react with carboxy compounds in aqueous medium to form hydrazide. For the reaction to proceed under mild conditions, *N*-ethyl-*N'*-(3-dimethylaminopropyl) carbodiimide (EDC) is required as a condensing reagent. Fatty acids are determined with 2-nitrophenylhydrazine hydrochloride (NPH) by LC-UV detection. The detection limits for long chain fatty acids are 2.5–5 pmol per injection. As FL derivatization reagents, 6,7-dimethoxy-1-memyl-2(1*H*)-quinoxalinone-3-propionyl carboxylic

acid hydrazide (DMEQ-PAH), 2-(hydrazinocarbonylphenyl)-4,5-diphenylimidazole (HCPI), and 4-(5,6-dimethoxy-2-benzimidazol)benzohydrazide (DMBI-BH) are developed (Figure 9). Hydrazides can be detected at the femtomole level by LC-FL detection. DMEQ-PHA and HCPI are applied for the determination of fatty acids by PO-CL detection with the detection limits in the range of subfemtomole to femtomole. 2,4-Dinitrophenylhydrazine (DNPH) has been used as a precolumn reagent for LC-ECD.

Reagents having bromomethyl group reacts with carboxy compounds in acetonitrile or acetone to form the corresponding esters. Crown ether and potassium ion, or organic bases such as triethylamine and ethylamine, catalyze the reaction. 4-Bromomethyl-7-methoxycoumarin (Br-MMC) is a typical reagent. Br-MMC has been widely used for the derivatization of fatty acids, dicarboxylic acids, prostaglandins, bile acids, and glucuronic acids. Detection limits reported are in the range of picomole by UV detection to femtomole level by LIF detection. Other analytical reagents having a bromomethyl moiety are 4-bromomethyl-6,7-dimethoxy-1-methyl-2(1*H*)quinoxalinone (Br-DMEQ), 3-(bromoacetyl)-7-diethylaminocoumarin (Br-DAC), and 4-bromomethyl-6,7-dimethoxycoumarin (Br-MAC).

Reagents having diazoalkyl group react with carboxylic acids to form the corresponding ethers (Figure 10). 9-Anthryldiazomethane (ADAM) has been utilized for the LC–FL determination of carboxylic acids in biological samples. In spite of the instability even at  $-10^{\circ}\text{C}$ , ADAM has been applied for the determination of many biological carboxylic acids such as fatty acids, prostaglandins, oxalic acids, amino acids, and carnitines. Picomole level detection can be achieved with fluorescence detection. As similar type of reagents, 1-pyrenyldiazoraethane (PDAM) and 4-diazomethyl-7-methoxycoumarin (DAM-MC) have also been synthesized.

*p*-Methoxyaniline and 1-naphthylamine (1-NA) are used for the determination of fatty acids. The resulting derivatives are separated by RP-LC, and detected with UV absorption. Fluorescence derivatization reagents *N*-(1-naphthyl)ethylene diamine (NEDA) and 2-[*p*-(5,6-methylenedioxy-2*H*-benzotriazol-2-yl)]phenethylamine (MBPA) have also been developed.

The reagents containing hydroxy group have been developed for FL derivatization of carboxylic acid or other activated acids. 1-Pyrenemethanol (1-PM), 4-hydroxymethyl-7-methoxycoumarin (HMC), and 5-(4-pyridyl)-2-thiophenemethanol (PTM) have been applied to carboxylic acids with LC–FL detection.

Trifluoromethanesulfonate derivatives such as 2-(2,3-naphthalimido)ethyl trifluoromethanesulfonate (NE-OTf) and 2-(2,3-antrathenedicarboxyimide)ethyl trifluoromethanesulfonate (AE-OTf) can be used for LC determination of carboxylic acids. Thermolabile carboxylic acids in mouse brain are determined by NE-OTf with the detection limits of hundreds of femtomoles by UV detection, and a few femtomoles by FL detection.

Many benzofurazan reagents have been synthesized for labeling of carboxylic acids, e.g., 4-(aminosulfonyl)-7-*N*-(2-aminoethylamino)-2,1,3-benzoxadiazole (ABD-AE), 4-(*N,N*-dimethylaminosulfonyl)-7-carverino-2,1,3-benzoxadiazole (DBD-CD), 4-nitro-7-(2-carbazoylpyrrolidine-1-yl)-2,1,3-benzoxadiazole (NBD-ProCZ), etc.

## Thiol Group

Thiol group-containing compounds are widely distributed in industrial, urban waste, and biological materials. The analysis of thiol contents in biological molecules gives valuable information in pharmacodynamic studies of drugs and in diagnosis of some diseases.

As selective reagents for thiol group, *N*-substituted maleimides, active halogen, and aziridine have been reported.

Maleimides easily react with thiols at pH 5–8 as shown in Figure 11. The typical analytical

**Figure 10** Reaction scheme for ADAM with carboxylic acid and diazoalkyl analytical reagents.

**Figure 11** Reaction scheme for DBPM with thiol compound and maleimides analytical reagents.

maleimide-type reagents *N*-[*p*-(2-benzoxazolyl)phenyl]maleimide (BPM), *N*-[4-(6-dimethylamino-2-benzofuranyl)phenyl]maleimide (DBPM), and *N*-(9-acridinyl)maleimide (NAM) have been developed. These reagents are mainly used as precolumn reagents for LC–FL detection. The advantageous features of these reagents are that they do not have significant fluorescence properties themselves, but after reaction with thiols the derivatives show high fluorescence. The sensitivities of these reagents are in the range of picomole levels for thiols. However, as the products produced are not stable and easily convert to fluorescent ring-cleaved compounds, two peaks sometimes appear in the chromatogram. DBPM can be applicable for the determination of six kinds of thiol-containing compounds in biological fluids. The derivatives are detected sensitively by LC with FL and PO–CL detections. *N*-(4-Anilinophenyl)maleimide (APM) and *N*-(ferrocenyl)maleimide, which have favorable electrochemical properties, are synthesized as analytical reagents for LC–ECD.

Halogenobenzofurazan, e.g., 7-fluoro-2,1,3-benzoxadiazole-4-sulfonate (SBD-F), 4-(aminosulfonyl)-7-fluoro-2,1,3-benzoxadiazole (ABD-F), and 4-(*N*,*N*-dimethylaminosulfonyl)-7-fluoro-2,1,3-benzoxadiazole (DBD-F), having reactive fluorine groups are synthesized. The application studies of these reagents on the determination of cysteine, GSH, and other thiol compounds by LC–FL detection have been reported with detection limits at the subpicomole level.

Bimane derivatives containing active halogen react with thiol compounds to form fluorescence thioethers. This reaction proceeds under relatively mild conditions, i.e., pH 8 at room temperature in 5 min. Monobromobimane and monobromotrimethylaminobimane as precolumn derivatization reagents

for biological thiols are used in LC with FL detection. The resultant derivatives from CoA, acyl-CoA, and *N*-acetylcysteine can be detected at the picomole level.

Reagents having aziridine group selectively reacts with thiol compounds to produce thioethers, which accompany with the cleavage of the aziridine ring. 5-Dimethylaminonaphthalene-1-sulphonylaziridine is used as a precolumn derivatization reagent. The determination of amino acids containing thiol group and penicillamine has been achieved with detection limits at the picomole level.

OPA reacts with thiols and amines to form highly fluorescent isoindole compounds as described in the section on ‘Amino group’. The analytical methods using OPA have been reported for pre- and post-column derivatization of amino acids. These methods are very sensitive and afford detection as low as 25 fmol.

Ellman’s reagent, 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB), produces 2-nitro-5-sulphydrylbenzoic acid by the reaction with thiols, which shows visible absorption at ~412 nm. Acetyl-CoA thioester is separated by ion-pair LC followed by conversion to thio-CoA with a postcolumn immobilized enzyme column reactor of phosphotransacetylase. Thio-CoA thus liberated can be determined spectrophotometrically after reaction with Ellman’s reagent with the detection limit of 0.05 nmol.

## Halogen Group

Organic compounds containing aryl halides are widely spread in the environment, foods, and biological materials, and is a serious health concern.

**Figure 12** The reaction for aryl halides with DPA.

In general, aryl halides can be directly analyzed by GC-ECD or LC-UV detection. GC methods have higher performance in separation and detection than that achieved by LC methods. Many practical applications are attained by GC methods. However, there are few reagents for selective and sensitive determination of aryl halides. Recently, an anticancer drug, prosopidin, was determined in a biological sample by CZE after labeling with diethyldithiocarbamic acid (DDTC). The derivative is detected at 254 nm with the detection limit of 5 fmol on-column. However, disadvantages of this method are that  $\sim 10$  times excess of reagent and  $\sim 1.5$  h of reaction time are required to complete the derivatization. More recently, the derivatization method for aryl halides with a fluorescent arylboronic acid, 4-(4,5-diphenyl-1H-imidazol-2-yl)phenylboronic acid (DPA), based on Suzuki's coupling reaction, was developed. This reaction proceeds in the presence of palladium(II) acetate, 2-(dicyclohexylphosphino)biphenyl, and potassium fluoride in dioxane (**Figure 12**). The derivatives are separated by LC and detected fluorometrically at 410 nm with excitation at 320 nm. The detection limits for aryl halides are at sub- and low-picomole levels.

## Applications

### Determination of Catecholamines and Their 3-O-Methyl Metabolites

Catecholamines (CAs) are known to be important biogenic amines and are present in extremely small

amounts in human body as neurotransmitters or hormones. A highly selective and sensitive reagent is required for the determination of CAs in biological samples, where many of their precursors and metabolites coexist. An LC-ECD method is often used for the determination of CAs. Although the sensitivity of this method is enough to determine CAs in biological samples, its selectivity and stability are not satisfactory. On the other hand, the ethylene diamine (ED) method has been reported as highly selective for CAs (**Figure 13**). The reaction is suited for the simultaneous detection of CAs, because all the CAs are reactive with ED to yield strong fluorescent compounds. The derivatization method for CAs with ED followed by FL detection can be used as a good alternative for the direct amperometric detection of the catecholic compounds. Recently, a highly sensitive method based on the reaction described above for simultaneous determination of CAs and their 3-O-methyl metabolites was developed by utilizing the PO-CL reaction and semi-microcolumn LC. The automated LC system consisted of four LC pumps, an autosampler, a rotary six-way valve, a precolumn, an analytical column C18 ( $250 \times 1.5$  mm, ID), a coulometric cell, a reaction coil ( $0.25$  mm (ID)  $\times 6.5$  m) in a thermostatically controlled bath ( $80^\circ\text{C}$ ), and a chemiluminescence detector. ED as a fluorogenic reagent and a mixture of TDPO,  $H_2O_2$ , and TFA as a chemiluminescence reagent are used. By this method, CAs and their 3-O-methylmetabolites in mouse plasma of a very low volume of  $15\ \mu\text{L}$  can be determined. The quantification limits for CAs (norepinephrine, epinephrine, and dopamine) and

**Figure 13** Reaction scheme for catecholamines with ethylene diamine.

their metabolites (normetanephrine, metanephrine, and 3-methoxytyramine) are in the range of subpicomole levels.

#### Determination of Polyamines Based on Intramolecular Excimer-Forming Fluorescence Derivatization

Polyamines having two to four amino groups occur in all eukaryotic cells and play important roles in cell growth and differentiation. These compounds can be determined with analytical reagents for amines described above. A unique approach of fluorescence derivatization method for polyamine has been reported. This method is based on an intramolecular excimer-forming fluorescence derivatization with a pyrene reagent, 4-(1-pyrene)butyric acid *N*-hydroxysuccinimide ester (PSE). All primary and secondary amines in polyamine molecule are labeled with PSE to form the corresponding dipyrene- to tetrapyrene-labeled derivatives (Figure 14). The derivatives afford intramolecular excimer to fluoresce, which can clearly be discriminated from the monomer fluorescence emitted by PSE, its hydrolysate, and monopyrene-labeled derivatives of monoamines (Figure 15). The PSE derivatives of putrescine, cadaverine, spermidine, and spermine can be separated by a reversed-phase LC on a  $\text{C}_8$  column with a linear gradient elution. The detection limits for the polyamines are at 1–8 fmol on-column.

The determination of basic amino acids such as lysine and ornithine, and triethylenetetramine, a therapeutic drug for Wilson's disease, in biological samples has been performed in the same manner.

**Figure 14** Inter-molecular excimer-forming fluorescence derivatization of polyamines with PSE. (Reprinted with permission from Chromatogram (2000). *Analytical Chemistry* 72: 4203; © American Chemical Society.)

#### Determination of Plasma Saturated Fatty Acids Using Pentafluorophenyldimethylsilyl Derivatives by GC-MS

The common fatty acids (FAs) of plant and animal origin contain several carbon atoms in their straight chains with a terminal carboxyl group. Some of the saturated FAs in tissues or body fluids are used as the qualitative biomarkers for fatty acids intake and peroxisomal disorders. GC-MS has been widely used for the determination of FAs in biological mixtures including their methyl, benzyl, and trimethylsilyl esters. The appropriate choice of derivatization in GC-MS with electron impact ionization is primarily concerned not only for GC properties, but also for the selection of efficient quantitative ions in the

**Figure 15** Chromatograms obtained with a standard mixture of the polyamines. (Reprinted with permission from Intramolecular excimer-forming. (2000). *Analytical Chemistry* 72: 4200; © American Chemical Society.)

selected ion-monitoring (SIM) mode. The GC–SIM–MS for saturated fatty acids (SFAs) as their flophemesyl ester derivatives has been developed for the detection of 11 SFAs including C12:0–C26:0 (even numbers only), C17:0, C19:0, and C23:0 in human plasma with stable isotope  $d_3$ -stearic acid as an internal standard. FAs derivatized with flophemesyl chloride at room temperature for 15 min are separated with a HP Ultra-2 (25 m  $\times$  0.2 mm, ID) fused-silica capillary column. The detection limits are in the range of 1–10 pg. This method can determine saturated FAs in plasma sample of normal subjects and patients with X-linked adrenoleukodystrophy, which is one of the hereditary peroxisomal disorders.

### Introduction

Gas chromatography (GC) is a dynamic method of separation and detection of volatile compounds. It was first introduced in the 1950s and rapidly

established itself as a routine analytical technique in most industrial and academic laboratories. From its introduction and until the advent of high-performance liquid chromatography, it dominated separation methods. This can be attributed to the capability for high resolution, selectivity, and sensitivity.

Separation in GC is achieved by partitioning of gaseous solutes between a typically inert gaseous mobile phase and a stationary liquid or solid phase retained in a column. These variants are described as gas–liquid chromatography (GLC) and gas–solid chromatography (GSC), respectively. With the exception of some specialized areas such as the analysis for inorganic gases, it is GLC which is used.

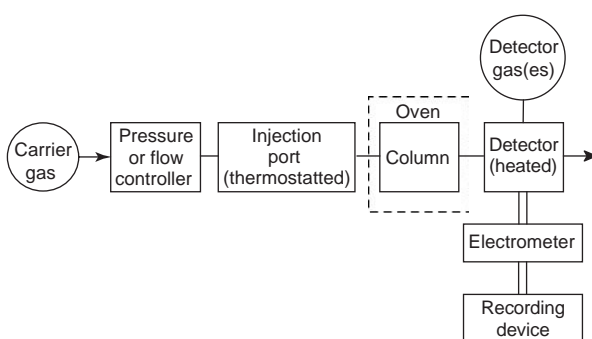

**Figure 1** A gas chromatogram showing the separation of a nine-component mixture. Peaks due to individual compounds are labeled 1 through 9. The unlabeled peak is attributed to the sample solvent. The retention time for individual components can be read from the chromatogram although it is generally provided in a separate report.

Nevertheless, the instrumentation is virtually identical for the two techniques.

In the most common approach (elution development), the sample is introduced into the chromatograph via the sample inlet into a continuous flow of mobile phase, which is referred to as the carrier gas. The sample is vaporized in the inlet system and transported by the carrier gas to the thermostatted column where separation occurs. The individual components give rise to an electrical signal in the detector that may have provision for the inlet of additional make-up gas. This is necessary to permit separate optimization of gas flow through the column and detector. After suitable amplification the detector signal is conducted to a recording device. The detector output is produced as a chromatogram (Figure 1). This is a plot of detector signal versus time in which individual peaks represent the separated components of the sample. Sample components can be identified from their characteristic retention times. With proper calibration, the amounts of the components of a mixture can be measured accurately also.

Figure 2 shows the essential components of a gas chromatograph as a block diagram. These parts can be identified as the carrier gas, sample introduction system, the column, the detector, and data acquisition system comprising an electrometer and integrator/recording device. Although not apparent from the figure, there are three separately controlled heated zones for the inlet, column, and detector in the typical instrument. An overview of some of these aspects

**Figure 2** Block diagram of a gas chromatograph.

is given in the following sections. The reader is also referred to the more detailed discussion of detectors and specific techniques such as pyrolysis GC, high-speed GC, and GSC. Extensive resources for training, method development, and support services are provided by a number of manufacturers of gas chromatographic instrumentation.

## Sample

It follows from the preceding discussion that the basic requirement with respect to sample is that it has an appreciable vapor pressure at the column temperature. As usually practiced, the sample must also be thermally stable. This allows the sample components to vaporize in, and move with, the gaseous mobile phase. This requirement is not as severe a restriction as it appears since column temperatures as high as 450°C (300°C is more common) are used in GC. Thus, GC can be applied to all permanent gases, most nonionized small- or medium-sized organic molecules (typically up to C30), and many organometallic compounds but it cannot be used for macromolecules or salts. In some instances, nonvolatile compounds can be converted into more volatile and stable derivatives before chromatography. In a typical sample containing a mixture of volatile and nonvolatile components, care must be taken that the nonvolatile solutes are not deposited in the system where they can interfere with subsequent analyses.

## Mobile Phases

Substances capable of interacting with the analyte and influencing selectivity have been used as carrier gases in rare instances. However, the ideal mobile phase for GC is usually nonreactive toward the analyte(s), nonflammable, cheap, and environmentally friendly since it is vented at the end of the instrument. Hence, the choice of a mobile phase or carrier

**Table 1** Physical properties (at 273 K and 101 kPa) of carrier gases used in gas chromatography

Gas	Thermal conductivity ( $10^8 \text{ W m}^{-1} \text{ K}^{-1}$ )	Viscosity ( $10^{-7} \text{ Pa s}$ )	Density ( $\text{kg m}^{-3}$ )
Hydrogen	16.75	84	0.0899
Helium	14.07	186	0.1785
Nitrogen	2.39	166	1.2505
Argon	1.67	212	1.7839
Neon	4.56	298	0.8999

gas is determined by practical constraints of cost, availability, inertness, and detector compatibility rather than its ability to effect a particular separation. The usual mobile phase in GC is therefore a noninteractive gas that does not influence selectivity. However, the carrier gas can influence resolution through its effect on column efficiency because of differences in solute diffusion rates for various gases. Moreover, it can effect analysis time and plays a role in pressure-limiting situations because of differences in gas viscosities (see **Table 1**).

Taking these considerations into account, hydrogen, helium, and nitrogen are the most popular carrier gases in GC. Carrier gases are usually supplied from a compressed gas cylinder. Gas purity is a major consideration and, in general, the highest purity gas should be used to reduce deterioration of the stationary phase and lessen detector noise. Moreover, it is usual to include oxygen and moisture traps in the carrier gas lines. These traps are commercially available, containing activated carbon (to remove organic impurities) or molecular sieves (for moisture and oxygen). The traps must be monitored and periodically regenerated. When changing cylinders, it is important to ensure that all fittings are free of dust and dirt particles before connection to gas lines.

Typical compressed gas cylinders contain a pressure of 20 MPa whereas supply line pressures to the gas chromatograph are more commonly in the range 50–300 kPa. Thus, appropriate regulators and controllers are used to step down and control the pressure and flow rate to the column. With traditional instruments, the carrier gas is regulated by either a pressure regulator or flow controller. The choice between the two is dependent on the inlet system and column type. In recent years, instrument manufacturers have introduced completely electronic programmable pressure-controlled gas chromatographs.

When a capillary column is installed in an instrument it should be checked for carrier gas flow before connecting the detector end of the column to avoid the possibility of heating a column with no flow.

When the column connection has been completed, the system should be checked for gas leaks. Once any leaks have been eliminated and the column purged with carrier gas, the volumetric flow rate ( $\text{ml min}^{-1}$ ) or the theoretically more useful average linear gas velocity ( $\text{cm s}^{-1}$ ) can be measured.

## Sample Introduction Systems

The injection port or inlet system is the next major component of the gas chromatograph. It must receive the sample and deliver the correct amount of material to the column so as not to exceed the sample capacity of the column or the linear range of the detector in use. Several types of inlet and sample introduction techniques have been developed to accommodate the diversity of sample types and particularly the state of aggregation of the sample and the range of columns. Specialized techniques include equilibrium headspace sampling, purge and trap sampling, pyrolysis GC, and multidimensional chromatography in which the sample entering the column differs from the composition of the original sample. However, in the more usual case, the material entering the column must have the same composition as the original sample. Additionally, the sample has to be delivered to the column as a sharp band.

The most common analysis involves injection of 1–3  $\mu\text{l}$  of a liquid into a heated inlet. This is accomplished by means of a microsyringe through a septum made of elastomer or rubber, which seals the inlet system as the syringe needle is withdrawn. Septa have a limited lifetime dependent on the mode of injection (automatic versus operator injection), the injector temperature, and the septum quality. They are available from a number of manufacturers and a good operating principle is to perform a separation with a solvent blank, particularly with a new batch of septa. Syringe injection is also applicable to gases (50–1000  $\mu\text{l}$ ) but reproducibility is relatively poor and a sampling valve is more common. Syringes are available from a number of manufacturers in various configurations; needle point style, length of needle, fixed or replaceable needle. Most needles are constructed of stainless steel but specialty fused silica needles are available for on-column injection. An important consideration in choosing a syringe is the correct needle length to ensure delivery of the sample at the correct position in the injection zone.

With packed columns, the sample solution is introduced via the syringe into the sealed injection port that is heated to a higher temperature than the column in order to assist vaporization. Sample discrimination, which can be regarded as a measure of how well the detected peak areas reflect the original

sample composition, is not a problem. On the other hand, the much smaller sample capacity and lower carrier gas flow-rates associated with capillary columns magnify the extent of any problems and these are manifest as sample discrimination. Thus, more attention has been given to detailed investigation of various injection techniques when using capillary columns. These include the use of a vaporizing injector (i.e., heated injection port), cold syringe needle injection, hot needle injection, and solvent flush technique. The hot needle and solvent flush techniques are about equally effective in reducing discrimination and are preferred over other methods.

Traditional sample inlet systems were constructed of metal, thus providing metallic surfaces where sample decomposition was possible during sample evaporation. Interchangeable glass liners in the inlet, which are available in a range of configurations, are now standard in practically every sample injection system involving evaporation of the injected sample. Capillary columns have a very low sample capacity, and to avoid overloading the stationary phase specialized injection systems have evolved. The more important of these are split injection, splitless injection, cold on-column injection, and programmed temperature vaporizer split/splitless injection. These variants have evolved to meet the diverse needs of sample type and analyte concentration. For instance, splitless injection is more suited to trace/ultratrace analysis than is split injection.

## Columns

In GC where the mobile phase is noninteractive, the column alone determines the selectivity of the separation. From its inception, up to the 1980s, almost all separations in GC were performed on conventional packed columns despite the demonstration by Golay in 1957 of much greater efficiency obtainable with capillary columns. However, the obvious advantages of capillary columns in terms of higher resolution, greater sensitivity (despite injection

of less solute), reduced analysis time (to achieve equivalent resolution), and greater chemical inertness were gradually recognized. More recently, polymer-clad flexible fused silica capillary columns with chemically bonded and/or cross-linked immobilized stationary phases have become commercially available at reasonable cost and this has led to the current popularity of capillary columns. These columns now routinely provide high efficiency, inertness, and reproducibility. Alternatively, some separation efficiency can be sacrificed by using shorter columns to achieve very rapid analyses.

Capillary columns are available from several manufacturers in a wide range of column internal diameters (0.1–1.0 mm), column lengths (5–50 m), and stationary phase film thicknesses (0.1–5.0  $\mu\text{m}$ ). Generally, sample capacity increases but the efficiency decreases as the internal diameter or film thickness increases. The larger bore capillary columns with internal diameters between 0.53 and 1.00 mm are termed wide bore or megabore capillary columns and these have similar capacities, but greater efficiencies, than packed columns (see Table 2).

The largest variation in properties between conventional packed columns and capillary columns is associated with the column permeability. For this reason, capillary columns offer much less flow resistance and can be used in much longer lengths. Ultimately, the comparison of different column types is between the efficient use of column head pressure. Thus, a packed column containing 10  $\mu\text{m}$  particles can generate 50 000 theoretical plates per meter but requires a head pressure of 20  $\text{MPa m}^{-1}$ , whereas a 70 m capillary column of 50  $\mu\text{m}$  internal diameter can provide over one million theoretical plates with a column pressure drop of  $\sim 2.2$  MPa.

The stationary phase distinguishes GSC from GLC. In the former it is a solid adsorbent whereas in GLC it is a liquid either coated on a solid support (packed column) or deposited directly on the column walls. GSC preceded GLC but has never achieved the same prominence. Nonetheless, GSC has some

**Table 2** Comparison of packed and capillary columns

Parameter	Column type			
	Packed	Microbore capillary	Capillary	Megabore capillary
Internal diameter (mm)	1/4 in	100 $\mu\text{m}$	200 $\mu\text{m}$	530 $\mu\text{m}$
Length (m)	0.5–3	5–50	5–100	5–100
Permeability ( $10^{-7} \text{ cm}^2$ )	1–50	300–20 000		
Film thickness ( $\mu\text{m}$ )	1–10	0.1	0.2–2	1–5
Carrier gas average linear velocity ( $\text{cm s}^{-1}$ )	2–4	20–30	20–35	20–40
Flow rate ( $\text{ml min}^{-1}$ )	50–60	0.2–0.5	0.2–2.0	3–5
Sample capacity (ng)	20 000	<5	20–500	1000–15 000

important application areas such as the separation of inorganic gases and low molecular mass hydrocarbons for which GLC shows little selectivity. The main adsorbents for GSC are based on silica, charcoal, alumina, or molecular sieves although the development of new adsorbents is continuing.

The liquids used as stationary phases in packed and capillary columns are closely related. Nevertheless, liquid phases in capillary columns are usually cross-linked and bonded and may exhibit slight differences in selectivity to nominally equivalent packed column materials. The selection and comparison of stationary phases is confusing for newcomers as some 300 phases are available and in excess of 1000 have been described in the literature. Nevertheless, a fairly limited set of packed columns will suffice in most laboratories while an even more limited set of capillary columns will satisfy the needs of most laboratories. Moreover, two forces have combined to contain the proliferation of phases. Firstly, the high efficiency of capillary columns has reduced the necessity for many selective liquid phases and, secondly, theoretical studies have aided in phase selection.

There are several factors to consider in selecting a stationary phase. General considerations include temperature limits of the stationary phase, column efficiency, and lifetime and detector compatibility. Since nonpolar phases generally give more efficient columns that also exhibit superior lifetimes, it is wise to use the least polar phase that provides satisfactory separation. Phases containing the specific element corresponding with element-selective detectors (e.g., cyanopropyl phases with an NPD detector; trifluoropropyl phases with an ECD detector) should be avoided where possible. These selective detectors will be substantially more sensitive to 'normal' column bleed with such phases.

The most difficult factor to assess is the ability of a phase to effect the desired separation. From this perspective, the selection of a stationary phase and column is a daunting prospect. In theory, the selection is based upon maximizing the difference in selectivity between the solutes toward the phase. The separation is increased by exploiting solute-stationary phase interactions that retard the progress of some solutes relative to others so as to increase their retentions. The types of interactions to consider are:

- London or dispersion forces which are weak and nonspecific;
- dipole-dipole interactions or dipole-induced dipole interactions; and
- acid-base interactions or proton transferring (or sharing) tendencies of either the solute or stationary phase.

In practice, experience of similar separation problems, literature data relating to the target separation, and availability of the column phases are often the factors that determine the choice of a particular phase and column for a specific application.

The ideal liquid phase has a low vapor pressure, high thermal and chemical stability, low viscosity, nonreactivity toward sample components, and a wide temperature operating range, extending from  $-80^{\circ}\text{C}$  to  $450^{\circ}\text{C}$ . The phase must exhibit reasonable solvent properties (i.e., dissolving power) for the solutes in order to ensure symmetrical peaks. Stationary phases can be divided into nonpolar, polar, and specialty phases. These differ in their ability to interact with solutes of different structure, i.e., their selectivity. The nonpolar phases contain no functional groups capable of specific interaction (e.g., hydrogen bonding or dipole interactions) with the sample. Here, interaction between solute and stationary phase is limited to dispersive forces, and components therefore separate according to their volatility with the elution order following the boiling points. Compounds that cannot be differentiated on the basis of their boiling points (i.e., they have similar or equal boiling points) require a different stationary phase for separation. To obtain the differentiation of solutes by forces other than dispersion, a polar phase containing groups capable of specific interactions with sample components is required. The elution order now depends on a combination of volatility and specific polar-polar interactions. The relative magnitude of the various interactions (dispersive, dipole, hydrogen bonding, and acid/base) determines the selectivity of the phase toward particular solutes. The selectivity and resolution of a separation can be optimized by choosing a stationary phase that exploits the different interactions.

Nonpolar phases include a variety of hydrocarbons, such as squalane or Apolane C87, or mixtures of long-chain *n*-alkanes such as Apiezon L. Polymers based on a silicon-oxygen-silicon backbone form the basis of the most widely used group of stationary phases. These linear polysiloxanes differ in their average molecular mass, thermal stability, and viscosity. The chemical difference lies in the substituent and degree of substitution on the silicon backbone. Polar phases have been prepared by substituting polar trifluoropropyl or cyano groups for the methyl groups of the dimethylsilicones. By incorporating different proportions of the polar groups, stationary phases with a wide range of polarities can be produced. Other polar materials include polyethylene glycols or polyoxiranes with the structure  $-(\text{CH}_2\text{CH}_2-\text{O})_n-$ .

Specialty phases have been developed for use with particular analytical techniques such as GC-MS

where low bleed phases are essential, to meet the needs of particular groups (e.g., United States Environmental Protection Agency methods), or to separate particular classes of solutes. Included in the latter are chiral phases and Carbowax phases modified for separation of acids and bases.

### Column Temperature

Column temperature is an important variable that must be controlled in GC. Thus, the column is housed in a thermostatted oven. For simple samples containing relatively few peaks, an appropriate column temperature can be determined experimentally to achieve the separation and isothermal analysis is suitable. Nonetheless, many samples contain components with a wide range of volatility and more volatile components are eluted rapidly with no resolution when analyzed isothermally at a high temperature whilst the analysis time is unacceptably long and later eluting peaks are very broad and may be lost as baseline drift when analyzed isothermally at a low temperature. For such samples, temperature programming in which the column temperature is ramped during the analysis is essential.

### Detectors

Online detection is an integral part of a gas chromatograph. The detector monitors the column effluent and produces an electric signal that is proportional to the amount of analyte being eluted. The output signal is recorded as a continuous trace of signal intensity against time. In principle, any physical or physico-chemical property of the analyte that deviates from the properties of the carrier gas can serve as the basis for detection. Thus, over 100 detectors for GC have been described but relatively few are in common use.

The operation and applicability of different detectors can be compared against several performance criteria. These criteria include the sensitivity, noise, minimum detectable quantity or detection limit, detector time constant and response time, and the selectivity of the response. For purposes of screening a sample of unknown composition, a universal

detector has definite advantages whereas a selective detector may aid in the identification of an unknown compound or a given class of compounds. Selective detectors are particularly useful for the analysis of complex mixtures, where the selectivity may greatly simplify the chromatogram through suppression of the response of many potentially interfering compounds.

Detectors can also be classified as destructive or nondestructive. With nondestructive detectors, the original chemical form of the analyte persists throughout the detection process. This is an obvious advantage when the analyte is required for further analysis. In destructive detectors, the process of detection involves an irreversible chemical change in the analyte. A more useful classification distinguishes detectors on the basis of the transducer mechanism as ionization, spectroscopic, etc.

A consideration of the characteristics discussed above and the needs of a particular analytical problem will determine the most appropriate detector for a given problem. A detector with a wide linear dynamic range and low detection limit will be adopted for the determination of trace components in addition to main components in a sample. On the other hand, the use of a selective detector is convenient if the trace components belong to a particular class of substance or possess some common functional group.

Of the many available detectors, the most common (Table 3) are thermal conductivity detector (TCD), flame ionization detector (FID), electron-capture detector (ECD), alkali-flame ionization detector (AFID or NPD), flame photometric detector (FPD), and mass selective detector. The TCD and FID are usually considered universal detectors as they respond to most analytes whereas the ECD, AFID, and FPD are the most useful selective detectors and give differential responses to analytes containing different functional groups. Note that this does not imply that the magnitude of the response of the universal detectors is constant to all analytes. The mass selective detector has the advantage of operation in either universal or selective detection mode whilst an infrared detector is a powerful tool for distinguishing isomers.

**Table 3** Classification of the most common gas chromatographic detectors

<i>Detector</i>	<i>Response</i>	<i>Optimal detection limit</i>	<i>Destructive</i>
TCD	Organic and inorganic solutes	5–100 ng	No
FID	All organic solutes except formic acid and formaldehyde	10–100 pg	Yes
ECD	Halogenated and nitro compounds	0.05–1 pg	No
AFID	P- or N-containing solutes	0.1–10 pg	Yes
FPD	P- or S-containing solutes	10–100 pg	Yes
Mass selective	General all-purpose detector that is replacing FID in a number of situations	Dependent on mode of operation	Yes

The first detector commercially available for GC, the TCD or katharometer, remains a consideration for situations requiring universal detection. The TCD responds to any compound, irrespective of its structure, whose thermal conductivity differs from that of the carrier gas. Hence, it is the only choice for detection of compounds to which other more sensitive detectors give a poor or negligible response. In particular, it is the standard detector for determination of inorganic gases such as the permanent gases, hydrogen, oxygen, nitrogen, carbon dioxide, carbon monoxide, carbon disulfide, and water.

The FID is the standard workhorse detector in GC. It consists of a stainless steel jet constructed so that carrier gas exiting the column flows through the jet, mixes with hydrogen gas, and flows to a microburner tip that is swept by a high flow of air for combustion. Ions produced by the combustion are collected at a pair of polarized electrodes, constituting a small background current that is the signal. When solutes enter the detector, they are combusted and the signal increases. The current produced is then amplified and passed to a recording device. Unlike the TCD, the FID gives virtually no response to inorganic compounds. Most organic compounds, however, give similar responses, which is approximately proportional to the total mass of the carbon and hydrogen in the analyte. A reduced response is usually observed with the first members of a homologous series and compounds with a large proportion of oxygen.

The popularity of the ECD can be attributed to the high sensitivity to organohalogen compounds, which include many compounds of environmental interest, including polychlorinated biphenyls and pesticides. It is the least selective of the so-called selective detectors but has the highest sensitivity of any contemporary detector. The NPD or thermionic ionization or emission detector is a modified FID in which a constant supply of an alkali metal salt, such as rubidium chloride, is introduced into the flame. It is a detector of choice for analysis of organophosphorus pesticides and pharmaceuticals. The FPD detects specific luminescent emission originating from various excited state species produced in a flame by sulfur- and phosphorus-containing compounds.

## Dual Detection

The simultaneous use of two or more detectors, whose outputs complement each other, can aid in compound identification by generating substance-characteristic detector response ratios. In some instances, the detectors are operated sequentially or, alternatively, the column eluate is split and passed separately to the individual detectors. The combination of a selective with a universal detector can provide information on both the whole sample and, at the same time, greater quantitative sensitivity on specific components.

## Introduction

Gas chromatography (GC) is the premier chemical separation method for volatile compounds. It

involves the passage of a carrier gas over a supporting solid or liquid phase in a chromatographic column, with the carrier gas causing the compounds to move along the support material from the injector to the detector. These compounds must possess the physical property of having a given vapor pressure at the temperature of analysis, which in turn permits them to have the necessary concentration in the gas phase to allow them to travel along the GC column when a carrier gas flows along the column.

The GC experiment involves setting of conditions for carrier gas flow and the temperature of analysis, and selecting appropriate column properties. Column-based parameters include choice of packed or capillary format, column dimensions, and stationary phase and/or support. For all practical purposes, today analytical GC is conducted using capillary GC columns. There are only a few niche applications for which packed column GC is the preferred method. This includes preparative GC studies, selected catalyst studies, some inverse GC methods, and methods that might involve simple separations where larger volumes can easily be applied to the GC column. **Figure 1** shows the delineation of the two approaches, and **Table 1** compares various properties for packed and capillary columns for the specific case of analysis of fatty acid methyl esters, whilst **Table 2** reports selected properties of different modes of GC. Note that PLOT columns, which have an adsorbent phase fixed to the capillary wall, are primarily suited to permanent gases and other very volatile compounds. SCOT columns were originally developed to allow ease of coating thick film phases to the capillary, but this requirement is less important today as improved coating procedures are available. However, very polar phases may still present a challenge to capillary column manufactures, and so the range of phases is not as extensive as is available for packed column GC.

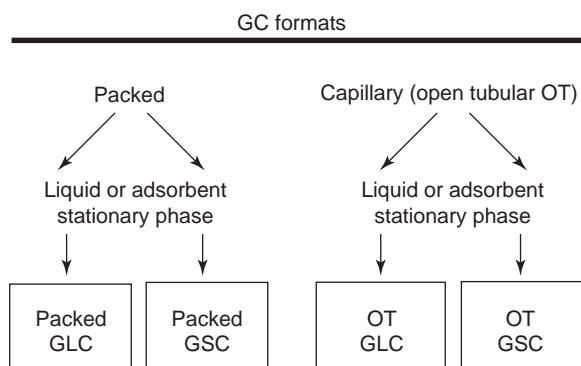

## Introductory Relationships of GC

The basic equation that determines the suitability of a compound to undergo gas chromatographic elution

is given by the relationship between distribution constant,  $K$ , and concentrations of solute in each phase of the GC column, at the temperature of the experiment:

$$K = C_S/C_M \quad [1]$$

The concentration terms,  $C_S$  and  $C_M$  (in stationary and mobile phases, respectively), here depend upon the specific type of phase employed in the experiment.

**Figure 1** Gas chromatography is often used in packed column or capillary column modes, with either a liquid or adsorbent stationary phase. GLC, gas–liquid chromatography; GSC, gas–solid chromatography.

**Table 1** Comparison of properties for packed and capillary columns for analysis of fatty acid methyl esters by using a diethylene glycol succinate (DEGS) phase, at 180°C

Column property	Packed column	Capillary column
Length $L$ (m)	2.4	100
Average linear carrier gas velocity $\bar{u}$ (cm s <sup>-1</sup> )	8	16
Unretained peak time $t_M$ (s)	30	625
Retention time $t_R$ (methyl oleate) (min)	29.8	38.5
Retention factor $k$ (methyl oleate)	28.5	2.7
Theoretical plates $N$ (methyl oleate)	3300	294 000
$R_s$ , methyl oleate and methyl stearate	1.5	10.6
Plate height $H$ (methyl oleate) (mm)	0.73	0.34

Adapted from Ettre LS (1979) *Introduction to Open Tubular Columns*. Norwalk, USA: Perkin-Elmer Corp.

**Table 2** Selected general properties of different modes of gas chromatography

Mode	$L$ (m)	ID (mm <sup>a</sup> )	$d_f$ (μm)	Phase ratio $\beta$	$H_{min}$ (mm)	$N$ (m)
Packed	2–5	2–4	5–20% w/w load	10–30	0.5	2000
SCOT	15–20	0.3–0.53	1.0+	20–100	0.5–1.0	1000–2000
PLOT	30	0.3–0.53	NA <sup>b</sup>	NA <sup>b</sup>		1000+
WCOT	10–60	0.05–1.0	0.05–5.0	15–250	0.05–1.0	2000–15 000

<sup>a</sup> Capillary columns traditionally have the following IDs: 0.05, 0.1, 0.15, 0.22, 0.25, 0.32, 0.53, 1.0 mm.

<sup>b</sup> PLOT columns have an adsorbent phase, so film thickness and normal  $\beta$  value cannot be determined.

SCOT = support-coated open tubular column. These columns are less popular today since thicker WCOT phases are now available.

PLOT = porous layer open tubular column.

WCOT = wall-coated open tubular column.

Clearly,  $C_M$  can be represented as the moles/volume concentration in the gas phase. Where the stationary phase is a liquid (or more likely, a polymer phase),  $C_S$  can be represented as moles/volume concentration in the liquid phase. However, for a gas–solid chromatography case, the stationary phase is an uncoated solid, and  $C_S$  will be related to the adsorption of solute onto the support, which is a surface sorption phenomenon. In this case,  $C_S$  will be moles/unit surface area on the solid phase.

Hence, eqn [1] can be rewritten as

$$C_S/C_M = n_S/V_S(V_M/n_M) = (n_S/n_M)(V_M/V_S) = k\beta \quad [2]$$

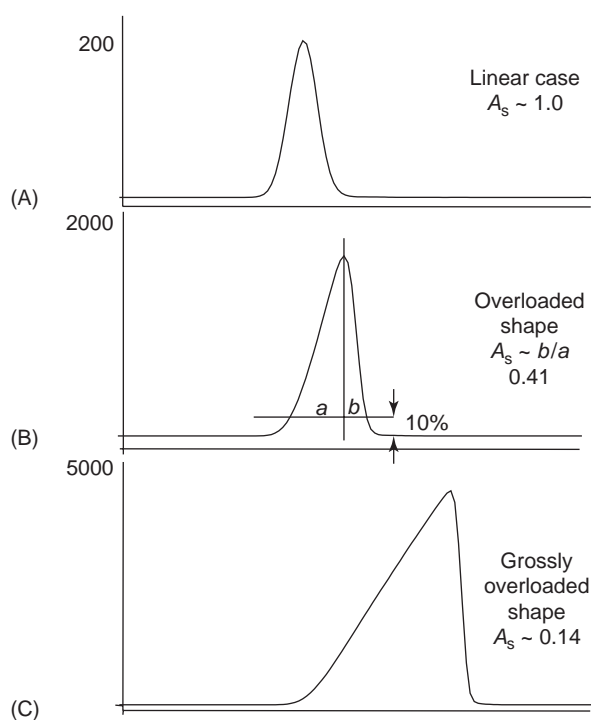

where  $n_S/n_M$  are number of solute moles in the two phases, with corresponding volumes  $V_S$  and  $V_M$ . Thus, a primary equation of chromatography is

$$K = k\beta \quad [3]$$

Since  $K$  is related to the concentration equilibrium of solute between the two phases, it follows that if more solute is introduced into the column, then for  $K$  to be constant, both  $C_S$  and  $C_M$  should increase proportionally. This means that  $k$  then must be a constant value (note that  $\beta$  must be constant, since it only depends on the column properties) and so retention time will also be constant. Since more sample is introduced, the chromatographic peak will be larger, but will be symmetric and located at the same time as for smaller injected amounts. This corresponds to linear chromatography conditions, and explains why retention time is a constant property of the solute provided linear conditions are maintained. **Figure 2** illustrates that linear chromatography arises when  $K = \text{constant}$ . Clearly there is a limit to how much solute can be introduced into a column and produce the same retention time – i.e., has a symmetric peak shape. Excessive injected solute will cause nonlinearity, and the peak shape will become nonsymmetric. Usually in gas–liquid chromatography, the peak shape will be a fronting shape, which becomes increasingly triangular with larger amounts injected. The reason for this effect is that the gas phase has limited ability to accept vapor of the solute and becomes saturated under those conditions (vapor phase overload). The equilibrium condition is no longer maintained, and the amount of solute in the stationary phase is more than it should be for an equilibrium case. This causes the peak maximum of the solute to be retarded compared with the linear case, so retention increases. **Figure 3** shows the progressive increase in peak asymmetry ( $A_s$ ; see **Figure 3B**) as more solute is introduced onto a capillary GC column, with the increase in response and total area confirming the greater amount of solute injected, and the increase in  $t_R$  arising from overloading. In **Figure 2**, the concave

**Figure 2** Isotherms in gas chromatography.

**Figure 3** (A) Symmetric peak shape and (B), (C) Progressively more overloaded peak shapes for a convex isotherm.

isotherm explains this effect ( $C_M$  limited). For gas–solid chromatography, the tendency for the solid phase is to be more readily saturated at higher injected amounts (there is limited surface area to accept solute under near to equilibrium conditions) and so the excess solute will tend to be forced into the gas phase, leading to a peak shape opposite to that for the overloaded gas–liquid case. Note that this can be seen for phases with some degree of adsorption, such as enantioselective phases with guest–host cyclodextrin additives.

## Efficiency of GC Columns

Efficiency is essentially the duration that a solute has been exposed to the chromatographic process compared with the narrowness of the solute band that results:

$$N = (L/\sigma)^2 \quad [4]$$

Since the chromatographic peak can be approximated by a normal distribution, the width of which can be expressed as its standard deviation, then the bandwidth is best reported as the peak variance,  $\sigma^2$ . Hence, the length measure is given as  $L^2$ . This can be measured in terms of distance units along the column, the time of the process, or obtained by directly measuring the recorded chromatogram. All these are equivalent measures, but the most useable and common method is to use the time basis, since these are given by the chromatographic report:

$$L = t_R \quad \text{and} \quad s = 4w_b \quad \text{or} \quad 2.35w_h \quad \text{or} \quad 2w_i \quad [5]$$

where  $w_b$ ,  $w_h$ , and  $w_i$  are peak widths at base, half-height, and the inflexion point, respectively. Hence,

$$\begin{aligned} N &= 16(t_R/w_b)^2 \quad \text{or} \quad N = 5.54(t_R/w_h)^2 \\ \text{or} \quad N &= 4(t_R/w_i)^2 \end{aligned} \quad [6]$$

This is shown schematically in Figure 4, with the other peak parameters defined in Figure 5. The inflexion lines to the peak intersect at  $1.213h$  and pass exactly through  $w_i$ , and this aids the correct lines to be drawn. The usual chromatographic data system will give retention time, total peak area, height, and peak-width at half-height ( $w_h$ ). Hence, calculating  $N$  based on  $t_R$  and  $w_h$  is easiest.

Theoretical plates calculation uses retention from the time of injection ( $t=0$ ). This means that even a peak eluting almost with the solvent or unretained peak will have quite good efficiency. But this is not really usable efficiency in terms of the ability to resolve peaks. It is often more realistic to represent efficiency in terms of effective plates, where  $t'_R$  is used in the respective formulas in eqn [6]. Thus, a peak eluting near the unretained peak has a low number of effective plates.

The  $N$  calculation above cannot be used for temperature programmed conditions. It is only relevant to isothermal operation. For temperature program analysis, it is more relevant to describe the quality of the chromatography column by resolution or Trennzahl (Tz). The latter is related to the separation number SN, which is calculated for the separation of successive pairs of a homologous series, such as

Figure 4 Parameters of a normal curve.

Figure 5 Typical chromatogram, showing retention terms.

normal alkanes:

$$SN = [(t_{R(z+1)} - t_{R(z)})/(w_{h(z)} - w_{h(z+1)})] - 1 \quad [7]$$

This essentially describes how many solutes can be placed between the two series members. The better the efficiency of the column (i.e., narrower peaks), the larger will be the separation number. This can be used as part of a generalized quality measure of a column's quality.

For a capillary column, quality is also measured by the use of a standardized test mix, developed by Grob *et al.* (Figure 6). This mix is intended to provide qualitative information about the stationary phase coating, and in particular activity toward certain solutes. Thus, the mixture contains 2,3-butanediol, *n*-decane, 1-octanol, nonanal, 2,6-dimethylphenol, 2-ethylhexanoic acid, 2,6-dimethylaniline, *n*-dodecane,

**Figure 6** Typical results of the standardized Grob test, for determination of column quality. Mixture contents (and mass in the split method-injected solution, in  $\text{mg ml}^{-1}$ ) are: (1) 2,3-butanediol (0.95); (2) *n*-decane (0.43); (3) 1-octanol (0.555); (4) nonanal (0.625); (5) 2,6-dimethylphenol (0.485); (6) 2-ethylhexanoic acid (0.605); (7) 2,6-dimethylaniline (0.513); (8) *n*-dodecane (0.44); (9) methyl decanoate (0.605); (10) dicyclohexyl amine (0.51); (11) methyl undecanoate (0.59); and (12) methyl dodecanoate (0.578). The dotted line represents the expected peak maxima when each solute exhibits complete recovery, and excellent chromatographic behavior. (From Jennings W (1987) *Analytical Gas Chromatography*, p. 234. Orlando: Academic Press.)

methyl decanoate, dicyclohexylamine, methyl undecanoate, and methyl dodecanoate, although manufacturers often use other specific test mixtures. In this case, SN can be calculated between the homologous methyl esters. The peak shapes of various polar molecules (acidic/basic) and in particular attenuation of peak response is related to 'activity' of the column and may indicate that it is unsuited to particular analyses. The 2-ethylhexanoic acid solute is a stringent and possibly inappropriate test since the tendency to vapor phase overload almost inevitably leads to asymmetric fronting peaks on many stationary phases. The solutes are normally prepared in the test solution in amounts that produce very similar peak height responses for all solutes on a relatively nonpolar phase column (i.e., taking into account response factors and different peak broadening extents), which make the identification of peak attenuation relatively easy to recognize. Clearly, a different phase polarity will cause peak retention changes to what is shown in Figure 6.

## The van Deemter Equation

The van Deemter equation is the basic interpretive equation of column efficiency, which provides an insight into the factors that lead to broadening of a compound as it travels along the column. The equation considers various contributions to diffusion broadening of the chromatographic band, and so incorporates various terms that include diffusion coefficients in each of the phases. In its most basic form, the van Deemter equation can be written as

$$H = A + B/\bar{u} + C\bar{u} \quad [8]$$

These terms are referred to as the multiflow path (or Eddy diffusion; *A*), longitudinal diffusion (*B*), and resistance to mass transfer (*C*) terms, respectively.

A short comment on each is appropriate here.

The *A* term is a constant, independent of flow rate, which accounts for the effects of multipath flows in a column, and also may include the effects of injection and detection (i.e., extra column effects), which serve to broaden a peak. Note that this term is taken as zero for a capillary column.  $A = 2\lambda d_p$ , where  $d_p$  is particle diameter and  $\lambda$  is a packing factor.

The *B* term accounts for the effect of a solute undergoing diffusional broadening within the mobile phase. Clearly a band of gaseous molecules must spread apart relatively readily within the low density carrier gas as shown in Figure 7A where the gas phase distribution is superimposed in the figure, and so the higher the diffusion coefficient the greater the spreading. Hence,

$$B = 2\gamma D_M \quad [9]$$

where  $\gamma$  is a constant for tortuosity, which obstructs the longitudinal spread of the solute molecules. In a capillary column this constant will be unity.

The *C* term is a resistance to mass transfer term. Whilst this is sometimes referred to as the preference for a solute molecule to stay in the phase it is in, it can also be considered the effect of ease of crossing the phase boundary, from gas to liquid, or vice versa. Ideally, equilibrium across the phase boundary is established very rapidly, in order for the molecular distribution of the chromatographic band in the liquid phase to match that in the gaseous phase. If the reemergence of solute from the stationary phase is

**Figure 7** Representation of the  $B$  and  $C$  terms in capillary GC. (A) The  $B$  term leads to longitudinal diffusion (along the column) as shown by the superimposed distribution. (B) Mass transfer in the liquid phase (solutes re-emerging from the stationary phase) may be slow if the phase film thickness is large. (C) Mass transfer in the gas phase is aided by high diffusion coefficients in the gas phase (i.e., by use of  $H_2$  carrier gas) so that solute can migrate to the stationary phase and undergo equilibration processes.

slow compared to the linear velocity of the solute molecules along the column in the mobile phase, then there will be a natural broadening effect arising from this mass transfer process. There are two primary processes to consider – transfer from gas to liquid, and also liquid to gas. Hence, there should be at least two terms comprising  $C$ . The first is  $C_S$ , stationary phase mass transfer. This is a function of retention factor  $k$ , stationary-phase diffusion coefficient  $D_S$ , and incorporates phase film thickness,  $d_f$ . The equation often reported is:

$$C_S = 2/3[k/(1+k)^2]d_f^2/D_S \quad [10]$$

It is clear from schematic in **Figure 7B** that if the film thickness is large, the tendency will be for a solute which diffuses deeply into the stationary phase to lag the solute distribution in the gas phase. In the capillary GC experiment, provided  $d_f$  is small, this term may be neglected in preference to the mass transfer in the mobile phase:

$$C_M = [(1 + 6k + 11k^2)/96(1+k)^2][d_c^2/D_M] \quad [11]$$

where  $d_c$  is the diameter of the column. The important conclusions from this expression are that  $C_M$ : depends on the retention factor ( $k$ ) of a solute; is smaller for narrower ID capillary columns; and is inversely proportional to the diffusion coefficient in the mobile phase. In this case, the larger the  $D_M$  value, the smaller the plate height contribution. This can be rationalized by reference to **Figure 7C**. The

**Figure 8** van Deemter plot ( $H$  versus  $\bar{u}$ ) showing effects of individual terms  $A$ ,  $B/\bar{u}$ , and  $C\bar{u}$ . The most efficient conditions giving minimum plate height ( $H_{\min}$ ) at optimum flow velocity ( $\bar{u}_{\text{opt}}$ ) occur at the minimum of the van Deemter curve. Optimum practical gas velocity (OPGV) is located at  $\sim 2 \times \bar{u}_{\text{opt}}$ .

most important feature of the chromatographic bed in providing separation and efficiency is its ability to provide equilibration of the solute between the two phases. Thus, this term indicates that the faster the movement of the solute through the carrier gas (higher diffusion) or shorter mean free path to the phase surface (provided by a narrow column ID) the more efficient the outcome. For a common column diameter of 0.32 mm, the  $C_M$  term dominates the two mass transfer terms up to film thicknesses of 1–2  $\mu\text{m}$   $d_f$ .

The relative contribution of each of the above terms can be seen in the  $H - \bar{u}$  curve generated at different carrier gas velocities (**Figure 8**). The  $B$  term is dominant at low carrier flows, because excessive spreading in the carrier gas arises, and the low flow will mean that solute molecules in the gas and stationary phases will not be displaced very much in space arising from mass transfer effects. The  $C$  term is dominant at high flows because at high carrier velocities the solute molecules residing in the carrier gas will be carried a long distance along the column and therefore will be well displaced from the molecules that are held in the stationary phase, before each of them undergoes their next mass transfer equilibration. It is interesting that  $D_M$  appears in both the  $B$  term and the  $C_M$  term, but its effect on each is the opposite. For  $B$ , a low diffusion constant is desirable, but for  $C_M$ , a high  $D_M$  is desirable. Since it is often preferred that a column is operated at higher flow than optimum, such as at the OPGV (optimum practical gas velocity) defined as  $2 \times \bar{u}_{\text{opt}}$ ,

where faster analysis time is achieved without too much loss of efficiency, then the  $B$  term becomes less important and the properties that decrease  $C$  should be considered. This therefore suggests use of the carrier gas that decreases  $C_M$ , i.e., that which has the higher  $D_M$  – hydrogen – is the obvious choice. Thus,  $H_2$  is often the carrier gas of choice in high-resolution capillary GC analysis; it is also cheaper than the traditional helium carrier gas. An individual laboratory must evaluate concern regarding safety issues if  $H_2$  is to be used as carrier gas.

In his book (see Further Reading), Jennings presents a compilation of  $H - \bar{u}$  curves for a range of capillary columns that vary from short (5 m) and very narrow bore (0.05 mm), to long (60 m) and wide bore (0.53 mm ID) columns, as an aid to understanding optimization of the operational conditions.

## Variations to the van Deemter Equation

Two major variations can be made to the basic van Deemter equation. The first is a modification that makes it specific to capillary columns. By deleting the  $A$  term (the capillary column has no multifold path nature), the Golay equation is defined as

$$H = B/\bar{u} + (C_M + C_S)\bar{u} = B/\bar{u} + C_M\bar{u} \quad [12]$$

Note that the  $C_S$  term may also be deleted provided the above assumption of thin film stationary phase applies. The Golay curve will be as in Figure 8, but with no  $A$  term.

This can now give a number of useful interpretations of the performance of the capillary column. From the minimum of the Golay curve, the minimum plate height can be derived:

$$H_{\min} = 2\sqrt{BC} \quad [13]$$

For the case of the unretained solute,  $k=0$ , this is evaluated as

$$H_{\min} \sim 1/4d_c \quad [14]$$

Hence, for a column of 0.25 mm ID, methane should give a peak with  $\sim 15\,000$  theoretical plates per meter.

For a retained solute,  $k \neq 0$ , and an expression in  $k$  is derived:

$$H_{\min} \sim 1/4d_c \left[ (1 + 6k + 11k^2)/(1 + k)^2 \right]^{0.5} \quad [15]$$

This allows the best possible performance of a capillary column to be determined for any solute, under optimum conditions (i.e., at best flow velocity). Again, this depends on column inner radius ( $r_c$ ) and

**Table 3** Minimum plate height and maximum theoretical plates for capillary columns of various inner diameters

$d_c$ (mm)	$H_{\min}$ (mm)	$N_{\max}$ (plates $m^{-1}$ )
0.05	0.0354	28 200
0.1	0.0709	14 100
0.2	0.1418	7 050
0.22	0.1560	6 400
0.25	0.1772	5 600
0.32	0.2268	4 400
0.54	0.3828	2 600
1.0	0.7089	1 400

Data calculated for  $k=4$ .

solute retention factor. Table 3 lists optimum efficiencies for various capillary column inner diameters, for a solute with  $k=4$ .

This is a useful expression, since it provides a comparison of experimental performance against what might be expected theoretically. This can provide a measure of coating quality, or utilization of theoretical efficiency, %UTE. For a uniform, thin film coating, %UTE might be expected to be high (e.g., 80%). For a difficult to coat phase, a lower coating efficiency may be accepted for preparation of a capillary column.

The second variation arises from the use of conditions that affect the primary assumptions of the basic derivation of the van Deemter equation. There is an increasing interest in use of conditions that lead to fast analysis. This can be achieved by short, narrow bore columns, very high temperature program rates, and high carrier gas inlet pressure. Often, a combination of two or more of these may be employed. For higher phase ratios  $\beta$  (i.e., for thinner film phase coatings), shorter columns, or higher carrier velocities, a higher temperature programming rate ( $r_T$ ) can (should) be used for optimum performance:

$$r_{T\text{opt}} \propto \bar{u}\beta/L \quad [16]$$

It is accepted as a rule of thumb that optimum programming rate performance is taken as  $10^\circ\text{C min}^{-1}$  per unretained peak time (e.g., if  $t_M = 0.6$  min, then  $r_{T\text{opt}} \sim 10/0.6 = 16^\circ\text{C min}^{-1}$ ).

Hinshaw provides a useful comparison of experimental results arising from experiments where different isothermal temperatures are used, the temperature programming rate is altered, column length is altered, carrier gas flow rate is altered, and where column ID is altered to achieve equivalent resolution performance using a combination of a narrower and shorter column.

With the trend toward use of narrow columns, it has been proposed that the high-pressure drops that will be associated with generating reasonable carrier

gas flows will require modification of the Golay equation as follows:

$$H = B/\bar{u}^2 + C_M\bar{u}^2 + C_S\bar{u} \quad [17]$$

## Resolution of Solutes

Resolution is defined as

$$R_s = 2[t_{R(2)} - t_{R(1)}]/[w_{b(1)} + w_{b(2)}] \\ \sim \Delta t_R/w_b \sim \Delta t_R/4\sigma \quad [18]$$

This is a simple expression, which relates the difference in peak retention to their respective widths. Since the peaks will naturally be located closely, their widths will be similar so the second expression will be approximately the same as the first.

The greater the relative response difference between the two peaks, the less well can the smaller peak be recognized as the resolution diminishes. Figure 9 is a schematic diagram that shows the extent of overlap for different peak resolutions, for an equally abundant mixture (i), and a 1:4 mixture ratio (ii).

The resolution can also be expressed in terms of how well the peaks are separated in respect of their purities. The better the resolution, the more pure will be the peak (for example, if we were to collect each peak exactly to their valley point). Thus, Table 4 reports the peak purity of solutes A and B for different degrees of resolution.

A further important expression is the one that relates resolution to the column efficiency, relative

separation and retention;

$$R_s = 1/4(N)^{0.5}[(\alpha - 1)/\alpha][k/(k + 1)] \quad [19]$$

(where  $\alpha$  is relative retention  $t'_{R2}/t'_{R1} = k_2/k_1$ ). It is clear then that resolution doubles for a fourfold increase in column efficiency. This relation also holds for column length.

It is resolution that effectively determines the quality of an analysis. It has been shown above that performance of the column with respect to the ability to fit in resolved peaks between homologous series members at a given resolution is called the separation number. Here, the calculation of resolution, and the meaning of compound measurement quality is defined. It is clear that as measurement accuracy increases ( $R_s$  between neighboring compounds increases) fewer total analytes can be measured in a given 'separation space'. There is a point where increased  $R_s$  is no longer desirable, since the maximum measurement accuracy for quantitative measurement of a peak area will be reached, and the total analysis uncertainty is determined by other factors, such as injection precision. The usual minimum  $R_s$  is taken as 1.5, but a greater minimum  $R_s$  might be chosen for improved ease of quantitation or ruggedness of the separation. This requirement is much more critical for nondiscriminating detectors, from which solute-specific response criteria cannot be chosen (these might be termed single channel detectors). Thus, the flame ionization detector will not permit 'deconvolution' of individual peak responses for grossly overlapping peaks (note that chemometric deconvolution is a separate consideration). The mass spectrometer, however, is a multichannel detector, and may permit choice of specific ions that allow each component peak of overlapping peaks to be uniquely selected and their areas quantitated.

The ultimate chromatography requirement, however, is for resolved peaks, and hence the continual search for or development of methods that increase component separation. The separation space can be interpreted in respect of the peak capacity of the analysis. Peak capacity represents the theoretical total number of compounds that can be placed, at a given resolution, in the separation space. For a single dimension analysis, this will be (total analysis time)/(width of each resolved peak). Or

$$n_c = (1.5\Delta t)/(R_s w_b) \quad [20]$$

**Figure 9** Peak resolution plots for  $R_s$  values of (a) 2.0; (b) 1.5; (c) 1.0; (d) 0.8; (e) 0.625; (f) 0.5, and for situations of (i) two peaks A and B of equal size; (ii) peak A = 0.25 peak height of B.

**Table 4** Peak purity for different degrees of peak resolution, where purity is defined as the purity of each component that could be collected from an equally abundant mixture where sampling is taken to the valley point between the peaks (see Figure 9(i))

$R_s$	0.5	0.6	0.7	0.8	1.0	1.25
Peak purity	84	88	92	95	98	99.4

where  $n_c$  is the total peak capacity,  $\Delta t$  is the total analysis time, and  $w_b$  is the peak basewidth.

Since maximum use of separation power for a multicomponent sample is obtained in temperature programmed analysis, peak widths are often similar (although this is not exactly so). Taking, for example, a total analysis time of 60 min, and average peak width as 8 s at base (measured at  $4\sigma$ ), then  $(60 \times 60)/8 = 450$  peaks resolved at the  $4\sigma$  level can be fitted into the analysis. However, a sample that comprises 450 individual components will not have them uniformly distributed across the total analysis space, and so peak overlap will invariably occur. It has been deduced that when a sample contains more components than about 20% of the column peak capacity, randomly distributed throughout the separation space, then peak overlap will arise. Of course, most samples would not contain randomly distributed compounds, but they will be more likely clustered into a given region of the separating space, and this further reduces resolution.

Column efficiency is only one strategy for achieving peak separation, albeit an important one. Column stationary phase selectivity is another important parameter, and is best considered to be a primary parameter where there are only a few target solutes of interest, and where their elution properties are similar (i.e., they have similar retention times). Where there are a plethora of compounds, all of which are important, and they all show problem resolutions, it may be difficult to choose an optimum stationary phase that simultaneously achieves resolution of all these.

## Isothermal and Temperature Programming Operation

The temperature condition of analysis affects the vapor pressure or volatility of the solute in the experiment, and therefore the  $C_M$  value, and hence  $K$ . Since  $K = k\beta$ , then increased temperature gives reduced retention time. The  $\log(K)$  value decreases approximately linearly with increased  $T$ , and Figure 10 shows such a diagram. Note that at any given temperature, e.g., along the vertical line at 100°C, the homologous series of alkanes exhibit a constant increase in  $\log(K)$ , which is a general observation for homologous series in isothermal GC. The graph of  $\log(t'_R)$  versus carbon number is a straight line. Hence, the chromatographic result will show the alkanes or other homologues series members increase their retention times exponentially as the chain length increases. This observation is the basis for retention index calculations (see below).

**Figure 10** Effect of temperature on distribution constant ( $K$ ; proportional to retention factor,  $k$ ), for a series of  $n$ -alkanes. At any one temperature (e.g., 100°C here), the homologous series of compounds have logarithmically increasing  $K$  values.

Given that the relatively small boiling point range of the alkanes in the above example ( $C7 = 98^\circ\text{C}$ ; tridecane  $= 235^\circ\text{C}$ ) leads to a large difference in  $K$  and therefore retention difference of about 50-fold, it is impractical to analyze a mixture that contains a range of compounds of widely varying boiling points by using isothermal means. The appropriate method is to employ temperature programming oven conditions. Thus, at low-temperature operation, the more volatile compounds (lower boiling point) should have sufficient transport properties to permit them to elute, and as the oven temperature is increased, the compounds of higher boiling point are progressively increased in vapor phase concentration to allow them to also elute. Figure 11 represents the difference in results that will be observed in these two approaches for a mixture of homologous compounds. Figure 11A is an isothermal analysis that illustrates the increase in retention times of the members of the series, and the increase in peak width that accompanies this. In contrast, temperature programming will give a result similar to that in Figure 11B, with now an almost linear increase in absolute retention time from one member to the next, a similar peak width for each component, and if the same sample is analyzed as in Figure 11A, the resultant relative peak heights will be greater for the later peaks as their widths are comparatively decreased by a greater extent.

## Retention Indices

A single peak eluting from a GC column possess much information, but if not adequately described, this information may not be effectively communicated. The peak expresses both qualitative and quantitative information; however, as a single isolated line

**Figure 11** (A) Isothermal temperature conditions lead to an exponential increase in retention times for successive members of a series of homologous compounds. Peaks get broader, and for approximately equal amounts injected, their peaks will get smaller (assuming similar response factors). (B) Under temperature programmed conditions, peak widths are now similar over the elution range for the sample, and total analysis time can be reduced significantly compared with isothermal operation. Peaks should be approximately similar heights if the same amounts are injected. Here, it would be suspected that more of the later eluting compounds are present.

on a chromatogram the peak itself is almost meaningless. For instance, the peak area is useful only if the relationship between peak area or response, and amount of compound is established. So, also for the retention of a peak, this contains the essence of the compound identity, but only if the retention is reproducible from run-to-run, and if the retention has been classified against an 'elution scale'. It is also important to recognize that the absolute matching of retention time is a necessary, but not sufficient, criterion for confirmation of a component's identity. One compound must have a single retention time, but two or more compounds can have the same retention time.

It is important to compare reference standards and unknown samples under exactly the same conditions, preferably on exactly the same column (and it must be using the same stationary phase).

The retention index system of Kovats is one way to enhance the quantitative elution information of a compound on a particular column. It essentially relates the elution of a compound to that of a reference series of compounds, in this case the  $n$ -alkanes. The retention index  $I$  is formally calculated under

**Figure 12** Procedure for calculation of isothermal retention indices. See text for explanation.

isothermal conditions, according to:

$$I = 100n + 100 \times \frac{(\log t'_{RX} - \log t'_{RCn})}{(\log t'_{RCn+1} - \log t'_{RCn})} \quad [21]$$

where these values are defined in Figure 12.  $C_n$  is the  $n$ -alkane eluting just prior to solute X, and  $C_{n+1}$  the alkane eluting just after X. The procedure is a logarithmic interpolation. It is apparent that  $n$ -alkanes have retention index values of  $n \times 100$ .  $I$  values may be calculated by the mathematical calculation of eqn [21], or by plotting a graph of  $I$  versus  $\log t'_R$  for the  $n$ -alkanes, and then using this to find  $I$  for solute X from its  $\log t'_R$  value.

Other retention bases may be used for this approach; thus, homologous series of alcohols, ethers, esters, etc., might be used in place of the  $n$ -alkanes, which might not be so suited for use with especially polar phases. The specific example of fatty acids is an important analysis, and by using saturated fatty acid methyl ester (FAME) standards as the retention series, other FAME may be quantified in terms of their 'effective chain lengths (ECL)'. In this case, unsaturation of the FAMEs can lead to either longer or shorter retention than their saturated counterparts, depending on the stationary phase used, and so they will have noninteger  $I$  (or ECL) values.

When the available standards are not successive carbon numbers, but, for example only the even carbon-number compounds, eqn [21] may be modified by using  $t'_{RCn}$  and  $t'_{RCn+2}$  data, with interpolation within 200 index units.

Since much analysis is conducted under temperature programmed conditions, eqn [21] is modified by recognizing that absolute elution times are now

almost linear, with carbon number. Thus,

$$I = 100n + 100 \times [(t'_{RX} - t'_{RCn}) / (t'_{RCn+1} - t'_{RCn})] \quad [22]$$

It is important in all cases to specify the analysis conditions, such as the isothermal conditions and phase for eqn [21], and temperature program rate and phase for eqn [22].

For eqn [22], also called linear temperature programmed retention indices (LTPRI), a single temperature program ramp is most appropriate. These LTPRI values find particular application in essential oil analysis, where standard conditions have been developed by Adams, requiring a program rate of  $3^{\circ}\text{C min}^{-1}$ , and either a 5% phenyl dimethyl polysiloxane column, or a polyethylene glycol phase (note that LTPRI values are tabulated for each of these columns). Since the retention indices are not definitive by themselves, these are usually augmented by mass spectral library matching, with the two independent identification data providing a more secure confirmation of compound identity.

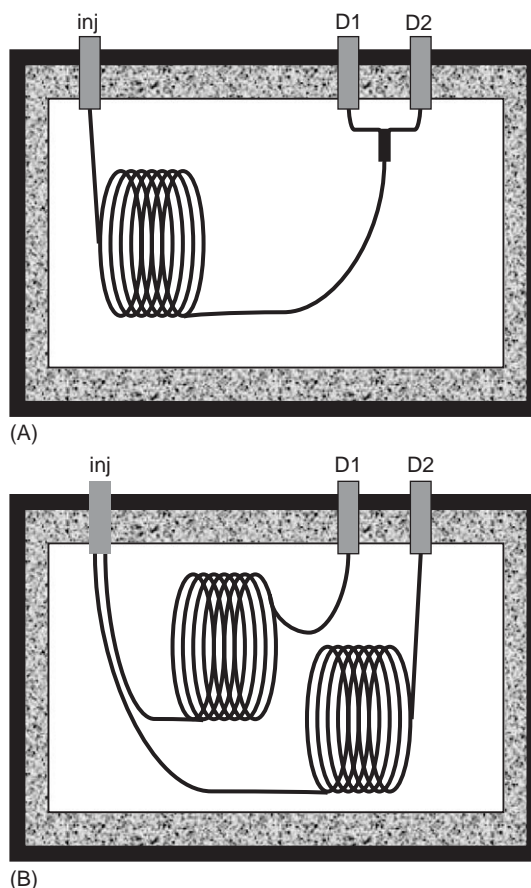

Retention indices find further application in characterization of stationary phases. Application of the concept of McReynolds uses a series of five solutes of differing chemical class (alcohol, aromatic, ketone, nitro, pyridine) to compare their retention indices on the test phase, against their retention indices on a stationary phase accepted to have very little 'polarity' (squalane). It can be argued that if a solute exhibits greater retention index on the test phase, then the intermolecular interactions between the solute and the phase are stronger than in the case when squalane is used, which means that the test phase should also exert a similar effect on similar solutes. Colloquially this is referred to as the 'phase polarity', and a scale may be set up according to the following:

$$\begin{aligned} \sum \Delta I = & \Delta I(\text{benzene}) + \Delta I(1 - \text{butanol}) + \Delta I(2 - \text{pentanone}) \\ & + \Delta I(1 - \text{nitropropane}) + \Delta I(\text{pyridine}) \end{aligned} \quad [23]$$

The larger the  $\sum \Delta I$  value, the larger the intermolecular interactions, the larger the phase polarity. This tends to be a rather imprecise measure of phase property, and how it is used in practice is not clear. Other descriptions are much more theoretically acceptable (refer to Poole's book, listed in the Further Reading) and are based on solute descriptors and allow more rigorous prediction of retention properties, but the above approach, being commonly used, relatively easily understood, and using the language of 'polarity' will make this concept difficult to supplant.

## Multiple Column Operation

As implied above, the use of two columns of disparate phases may provide useful supplementary results for identification. This is especially useful when the two phases have complementary resolution performance for compounds in a specific analysis. The expectation is that compounds not resolved on one phase may be resolved on the second phase, provided sufficiently different retention mechanisms are available on these phases for the compounds of interest. **Figure 13B** shows the possible instrument arrangement for a dual column–dual detector single injection analysis. Often the injectors will be the same if it is only the phase difference and therefore resolution differences that are of interest. It is necessary to have a well-characterized set of component overlap problems, so that routine data interpretation is possible. An alternative approach to obtaining two sets of retention data simultaneously is shown in **Figure 13A**, where outlet splitting of the effluent from the column

**Figure 13** (A) Dual detection analysis where the effluent from the single column is split into two different detectors. (B) Dual column analysis provides for different columns to be used to attempt to maximize resolution of components in complex sample analysis.

allows the response of two detectors to be acquired, where at least one of these will be a specific detector.

## Introduction

One of the major changes in the practice of gas chromatography over the last decade or so was the development of columns from being a highly skilled laboratory preparation procedure to a general laboratory supply item. Few laboratories prepare their own columns today and the general skills to do so are largely lost outside of the manufacturing facilities of the main suppliers of columns to the laboratory market. This became possible because of a gradual evolution in the understanding of the unit operations of column preparation procedures and their simplification together with the benefits of automation that made available high-quality columns at a reasonable price. On the other hand, this means that further developments in column technology are dictated more by market forces or the possibility of reducing manufacturing costs than exploratory science.

## Column Types

Wall-coated open tubular columns (WCOT columns), or simply capillary columns, and classical packed columns dominate the practice of gas–liquid chromatography today. Porous layer open tubular columns (PLOT columns) and classical packed columns dominate the practice of gas–solid chromatography. WCOT columns are typically up to 100 m

long with internal diameters of capillary dimensions coated with a thin, and usually immobilized, film of stationary phase leaving an open interior passageway down the center of the column. PLOT columns are identical to WCOT columns with the liquid phase replaced by a layer of fine adsorbent particles. WCOT and PLOT columns are the first choice for analytical separations because of their superior peak capacity and chemical inertness. Classical packed columns are usually 0.5–3 m long with an internal diameter greater than 2 mm packed with adsorbent or liquid-coated support particles of 100–250  $\mu\text{m}$  diameter. Packed columns offer a lower-cost alternative for some applications, are easier to use, are relatively tolerant of labile and involatile sample components, and are better suited to isolating preparative-scale quantities of materials. Only a limited number of stationary phases have been immobilized successfully in WCOT columns compared to the larger number and variety of stationary phases available for use in packed columns. Packed columns are generally preferred for the measurement of physicochemical properties of liquids and solids suitable for use as a stationary phase.

Micropacked, packed capillary, and support coated open tubular (SCOT) columns are rarely used today, having been superseded by developments in WCOT and PLOT column technology. Micropacked columns have diameters less than 1 mm and a similar packing density to classical packed columns. Packed capillary columns have an internal diameter less than 0.6 mm and are packed with particles of 5–20  $\mu\text{m}$  diameter. SCOT columns are capillary columns containing a liquid phase coated on a surface covered

allows the response of two detectors to be acquired, where at least one of these will be a specific detector.

## Introduction

One of the major changes in the practice of gas chromatography over the last decade or so was the development of columns from being a highly skilled laboratory preparation procedure to a general laboratory supply item. Few laboratories prepare their own columns today and the general skills to do so are largely lost outside of the manufacturing facilities of the main suppliers of columns to the laboratory market. This became possible because of a gradual evolution in the understanding of the unit operations of column preparation procedures and their simplification together with the benefits of automation that made available high-quality columns at a reasonable price. On the other hand, this means that further developments in column technology are dictated more by market forces or the possibility of reducing manufacturing costs than exploratory science.

## Column Types

Wall-coated open tubular columns (WCOT columns), or simply capillary columns, and classical packed columns dominate the practice of gas–liquid chromatography today. Porous layer open tubular columns (PLOT columns) and classical packed columns dominate the practice of gas–solid chromatography. WCOT columns are typically up to 100 m

long with internal diameters of capillary dimensions coated with a thin, and usually immobilized, film of stationary phase leaving an open interior passageway down the center of the column. PLOT columns are identical to WCOT columns with the liquid phase replaced by a layer of fine adsorbent particles. WCOT and PLOT columns are the first choice for analytical separations because of their superior peak capacity and chemical inertness. Classical packed columns are usually 0.5–3 m long with an internal diameter greater than 2 mm packed with adsorbent or liquid-coated support particles of 100–250  $\mu\text{m}$  diameter. Packed columns offer a lower-cost alternative for some applications, are easier to use, are relatively tolerant of labile and involatile sample components, and are better suited to isolating preparative-scale quantities of materials. Only a limited number of stationary phases have been immobilized successfully in WCOT columns compared to the larger number and variety of stationary phases available for use in packed columns. Packed columns are generally preferred for the measurement of physicochemical properties of liquids and solids suitable for use as a stationary phase.

Micropacked, packed capillary, and support coated open tubular (SCOT) columns are rarely used today, having been superseded by developments in WCOT and PLOT column technology. Micropacked columns have diameters less than 1 mm and a similar packing density to classical packed columns. Packed capillary columns have an internal diameter less than 0.6 mm and are packed with particles of 5–20  $\mu\text{m}$  diameter. SCOT columns are capillary columns containing a liquid phase coated on a surface covered

with a layer of solid support material, leaving an open passageway through the center of the column. Some characteristic properties of the different column types are summarized in **Table 1**. The most significant difference in kinetic properties is a result of differences in relative permeability. Open tubular columns provide much lower flow resistance and consequently can be used in longer lengths to obtain very high plate numbers compared with packed columns. The optimum mobile-phase velocity for open tubular columns is shifted to higher velocities compared with packed columns favoring faster separations.

### Column Properties

Narrow bore and thin-film WCOT columns afford the highest intrinsic efficiency per unit length and are selected for fast chromatography (**Table 2**). Since resolution increases only as the square root of the plate number, and also the column length, large values for the plate number are required for difficult separations. Such large numbers are available in gas chromatography, albeit at the expense of separation time, allowing separations to be achieved with only minimal differences in selectivity. In contrast to other chromatographic methods, separations in gas chromatography are often achieved through kinetic

optimization, allowing many separations to be obtained on a limited number of stationary phases.

At a given temperature, the partition coefficient is constant and the observed retention factor will depend on the phase ratio. The latter is defined as the ratio of the column volume accessible to the mobile phase and the volume of stationary phase. Columns with a large phase ratio provide small retention factors for volatile compounds and require inconveniently large plate numbers to provide adequate separations. Columns with a low phase ratio, that is, thick film columns, have a lower intrinsic efficiency than thin film columns, but provide better resolution of volatile compounds, because they provide more favorable retention factors. They also allow separations to be performed in a higher and more convenient temperature range than is possible with thin film columns. For high boiling compounds, columns with a low phase ratio are not useful because they lead to long separation times. Increasing the phase ratio by reducing the film thickness lowers the retention factors to a value within the optimum range so that there is little deterioration in resolution and faster separations are obtained. Packed columns have low phase ratios compared to WCOT columns. For compounds of moderate and low volatility separation times are longer.

**Table 1** Representative properties of different column types for gas chromatography

Column type	Phase ratio	$H_{\min}$ (mm)	$u_{\text{opt}}$ (cm s <sup>-1</sup> )	Relative permeability
Classical packed	4–200	0.5–2	5–15	1–50
Micropacked	50–200	0.02–1	5–10	1–100
Packed capillary	10–300	0.05–2	5–25	5–50
SCOT	20–300	0.5–1	10–100	200–1000
WCOT	15–500	0.03–0.8	10–100	300–20 000

$H_{\min}$  is the minimum plate height at the optimum mobile phase velocity  $u_{\text{opt}}$ .

**Table 2** Characteristic properties of some representative columns

Column type	Length (m)	Internal diameter (mm)	Film thickness (μm)	Phase ratio	Retention factor (k)	$H_{\min}$ (mm)	Column plate number	Plates per meter
Classical	2	2.16	10%(w/w)	12	10.4	0.55	3 640	1 820
Packed	2	2.16	5%(w/w)	26	4.8	0.50	4 000	2 000
WCOT	30	0.10	0.10	249	0.5	0.06	480 000	16 000
	30	0.10	0.25	99	1.3	0.08	368 550	12 285
	30	0.25	0.25	249	0.5	0.16	192 000	6 400
	30	0.32	0.32	249	0.5	0.20	150 000	5 000
	30	0.32	0.50	159	0.8	0.23	131 330	4 380
	30	0.32	1.00	79	1.6	0.29	102 080	3 400
	30	0.32	5.00	15	8.3	0.44	68 970	2 300
	30	0.53	1.00	132	0.9	0.43	70 420	2 340
	30	0.53	5.00	26	4.8	0.68	43 940	1 470

$H_{\min}$  is the minimum plate height and  $k$  is for undecane at 130°C.

## Column Preparation (Open Tubular Columns)

### Drawing Columns of Capillary Dimensions

Today, virtually all open tubular columns are prepared from fused silica and to a lesser extent borosilicate and soda-lime glasses. Fused silica is prepared by the oxidation of pure silicon tetrachloride in an oxygen plasma and is essentially pure silica, containing less than 1.00 ppm of metal impurities. The surface of fused silica glass is relatively inert, containing primarily silanol and siloxane groups. The presence of silanol groups is responsible for the residual acidic character of the glass. Because of its high melting point and ease of fracture, columns of capillary dimensions are drawn in a clean room facility at a rate of about  $1 \text{ ms}^{-1}$  from wide-bore silica tubes on a special apparatus, similar to those used for manufacturing optical fibers. The thin-walled tube must be protected immediately from moist air or dust particles that promote the growth of fissures or cracks. This is done by coating the outside of the capillary tube as it emerges from the softening furnace with a protective film of polyimide or aluminum. The drawn capillary column is inherently straight but sufficiently flexible to be coiled on a spool for collection purposes.

The thermal stability of the polyimide protective coating limits the application of fused silica capillaries for high-temperature applications. Typical polyimide coatings are stable to  $\sim 350^\circ\text{C}$  with some newer materials claimed to have a reasonable service lifetime at  $400^\circ\text{C}$ . Aluminum has excellent high-temperature stability but provides only modest protection of the fused silica. Fused silica capillaries are also limited for use in portable instruments and other applications where higher mechanical strength is desirable. Stainless steel capillary columns with an integral lining of silicon or fused silica provide the benefits of high-temperature stability and unsurpassed mechanical strength while approaching the low adsorptive and catalytic activity associated with fused silica. The fused silica layer of  $\sim 0.4 \mu\text{m}$  is prepared by the decomposition of an inorganic polymer in air and is intimately bonded to the oxidized metal surface.

Soda-lime and borosilicate glass capillary columns can be made in the laboratory using a glass drawing machine. The glass tube is fed into an electrically heated softening furnace at a controlled speed and drawn out at the lower end by a pair of motor-driven rollers. Capillary columns of different dimensions are drawn by maintaining a fixed differential between the feed rate of the stock tube to the furnace and the

pull rate of the softened tube at the exit of the furnace. The capillary tubing emerging from the softening oven is coiled by passage through a heated bent pipe. Unlike fused silica columns, these columns are relatively inflexible and require end straightening before installation in the gas chromatograph. The latter requires some skill. Altogether they are more difficult to handle and use than fused silica columns and require more extensive chemical treatment prior to coating with stationary phases. On account of these difficulties they are not as widely used as fused silica columns.

### Surface Treatments

During the drawing process the fused silica is subject to a range of temperatures resulting in a surface with an undefined silanol concentration that is also likely contaminated by trapped acidic impurities. Conditioning and hydrothermal treatment (acid leaching) are generally required to remove acid impurities and provide a uniform and defined silanol concentration for column preparation. These procedures are usually performed in the laboratory and are essential to minimize batch-to-batch variation in column properties.

The energy of smooth glass surfaces can be increased by chemical modification or roughening. Chemical modification is virtually the only approach used for fused silica columns while roughening and/or chemical modification is used with other glasses. The most important reactions are leaching with aqueous hydrochloric acid, etching by gaseous hydrogen chloride, whisker formation by hydrogen fluoride etching, and solution deposition of a layer of solid particles. Acid leaching under relatively mild conditions is used to optimize the concentration of surface silanol groups for uniform deactivation and possible bonding of the stationary phase to the fused silica surface. More aggressive conditions are often used with other glasses to form a silica-rich surface denuded of metal ions. This greatly diminishes the effects of glass variety and composition on subsequent treatments. Etching, a different process to leaching, is performed with dry hydrogen chloride gas and almost exclusively with soda-lime glass capillaries. This results in the formation of a regularly spaced array of sodium chloride crystals on the inner surface of the column. Whisker surfaces of different density are prepared by increasingly more aggressive reactions between hydrogen fluoride and the glass surface. A light etch is achieved by coating the column with a thin film of potassium or ammonium bifluoride solution and subsequent thermal treatment. For a high-density etch, higher temperatures and reaction with hydrogen fluoride gas, usually generated by the

*in situ* thermal decomposition of a film of a fluorine-containing ether is generally used. The area of whisker modified surfaces is about a 1000-fold higher than the smooth glass surface and consists of a densely packed layer of filamentary projections whose size and length depend on the experimental conditions. Whisker surfaces can be coated with almost any stationary phase but are very active, difficult to deactivate, and are intrinsically less efficient than columns prepared with less radical surface modifications. Particle deposition methods for surface modification rely upon the production of a uniform layer of fine particles obtained by coating with a stable sol, in the case of sodium chloride, or reaction between carbon dioxide and a thin film of barium hydroxide solution, in the case of barium carbonate. General problems with particle deposition layers are the difficulty of further deactivation and the lower intrinsic column efficiency compared with other methods.

Surface modification reactions used to improve the wettability of glasses by the stationary phase and to deionize some glasses result in an increase in the activity of the glass surface. Without subsequent deactivation, columns coated with low-polarity

stationary phases exhibit poor chromatographic properties manifested as tailing and even incomplete elution or decomposition of polar solutes. No universal deactivation method exists, but some techniques have emerged as more useful than others. The most widely used methods include high-temperature silylation using disilazanes or cyclosiloxanes, reaction with poly(alkylhydrosiloxanes), or reaction with the thermal degradation products of poly(siloxane) or poly(ethylene glycol) stationary phases (**Figure 1**). The R groups of the deactivating reagent, or a fraction of them, are generally chosen to match the substituents attached to the backbone of the stationary phase. Not all aspects of the deactivation mechanisms are understood. Although, there is probably a high commonality in the way the different reagents react. Above  $\sim 400^{\circ}\text{C}$  several alternative reactions compete with simple silylation. These include formation of siloxane bonds by condensation of neighboring silanol groups; nucleophilic displacement of the organic group from the surface-bonded reagent by a neighboring silanol group; and reactions with surface adsorbed water, forming short-chain polymers bonded to the surface. These reactions result in

**Figure 1** Reagents used for the deactivation of silanol groups on glass surfaces. A, disilazane; B, cyclic siloxane; and C, poly(alkylhydrosiloxane) in which R is usually a complementary group to the stationary phase (e.g., methyl, cyanopropyl, etc.). The lower portion of the figure provides a view of the surface of fused silica with adsorbed water (D), after deactivation with a trimethylsilylating reagent (E), and after treatment with a poly(alkylhydrosiloxane) reagent (F). (From Poole CF and Poole SK (1991) *Chromatography Today*. Amsterdam: Elsevier. With permission.)

a decrease in the number of silanol groups on the deactivated surface and the formation of a protective umbrella-type film, restricting access to the remaining unreacted silanol groups. Deactivation with poly(alkylhydrosiloxanes) occurs primarily by condensation with silanol groups on the fused silica surface with formation of surface-to-polymer bonds. In addition, physically adsorbed water hydrolyzes silane bonds to silanols, which react further with silane groups or other silanol groups to form a highly cross-linked resin film.

### Coating Techniques

The object of all coating techniques is the distribution of the stationary phase as a thin, even film that completely covers the glass surface. Dynamic coating and static coating methods, with several variations, are used for this purpose. Dynamic coating is commonly used for applying reagents for surface modification reactions, but since it does not allow control of the film thickness, it is not as widely used for coating the stationary phase. Dynamic coating is the only possibility for coating stationary phases of low viscosity. For dynamic coating, a suitable reservoir is charged with a solution of the stationary phase (or reagent) in a volatile solvent, from which a plug of solution is forced by gas pressure into the capillary, occupying perhaps 25% of the capillary length. The plug is then pushed through the column by gas pressure at a constant velocity aided by a buffer capillary attached to the outlet end of the column to be coated. When the plug has exited the column to be coated, the buffer capillary is disconnected, and the gas pressure increased to evaporate the solvent.

The static coating method yields efficient columns of predictable film thickness with gum or solid stationary phases. The column is filled entirely with a dilute solution of the stationary phase in a volatile solvent, which is then evaporated by sealing one end of the column and attaching the other to a vacuum source. The solvent is evaporated under quiescent conditions, leaving behind a thin film of stationary phase with a thickness that can be calculated from the column radius and concentration of the coating solution. The principal practical problem with the static coating method is the breakthrough of gas bubbles when the column is placed under vacuum or due to fluctuations of the column temperature during coating. The small cross-section of capillary columns means that the static coating process is relatively slow. Optimization of the coating solvent and the use of elevated temperatures are important for accelerating the process.

### Sol-Gel Techniques

Failure of any step in the multistep column preparation procedure discussed above is the main cause of poor column quality. Sol-gel technology affords a simpler and alternative approach for column preparation that is increasingly popular for self-prepared columns. The main advantage of the sol-gel approach is that it combines the individual steps associated with conventional column preparation into a single and reproducible process. Typically, the sol solution contains an alkoxide-based precursor, a hydroxy-terminated stationary phase, a surface deactivating reagent (if required), and a catalyst dissolved in a suitable solvent. The column is filled with the sol solution, and after an incubation period, simply expelled from the column, which is then dried, conditioned, and rinsed with solvent prior to use. The key sol-gel reactions involved in the coating procedure are: (1) catalytic hydrolysis of the alkoxide precursor; (2) condensation of the hydrolyzed products into a three-dimensional sol-gel network; (3) chemical bonding of the hydroxy-terminated stationary phase to the evolving sol-gel network; and (4) bonding of the evolving sol-gel polymer to the interior wall of the capillary. The stationary phase in this case differs from a conventionally coated liquid film column in two important aspects. The stationary phase is an inorganic-organic polymer with a structure that is different to a typical organic polymer and the stationary phase layer has a highly roughened surface of greater surface area than liquid film columns.

### Column Preparation (Packed Columns)

Packed columns, unlike WCOT columns, are easily prepared in the laboratory and many analysts prefer to prepare their own columns. Almost any liquid of low vapor pressure can be employed extending the scope of packed columns to stationary phases unavailable as WCOT columns, as well as allowing gas chromatography to be used to determine physicochemical properties of a wide range of materials evaluated as stationary phases.

### Supports

An ideal support would act like a sponge, holding the liquid phase as a thin film, without playing any further role in the separation process. Although no such ideal support exists, the diatomaceous earths provide a reasonable compromise of properties (Table 3). Diatomite (diatomaceous earth) is composed of the skeletons of diatoms, single-celled algae, which have accumulated in large beds in various parts of the

**Table 3** Characteristic properties of Chromosorb supports

Property	P	W	G	A	750
Color	Pink	White	Oyster	Pink	White
Apparent pH	6.5	8.5	8.5	7.1	8.0
Free fall density (g ml <sup>-1</sup> )	0.38	0.18	0.47	0.40	0.37
Packed density (g ml <sup>-1</sup> )	0.47	0.24	0.58	0.48	0.36
Surface area (m <sup>2</sup> g <sup>-1</sup> )	4.0	1.0	0.5	2.7	0.5–1.0
Maximum liquid loading (% w/w)	30	15	5	25	12

world. The skeletal material is essentially amorphous silica with small amounts of alumina and metallic oxide impurities. In their native form the diatomite skeletons are too small and fragile to be used as supports. Calcining at temperatures in excess of 900°C is used to agglomerate and strengthen the natural material. The presence of iron oxides gives this material its characteristic pink color. Calcining in the presence of a small amount of sodium carbonate results in the formation of a white material with most of the pore structure destroyed and metal impurities converted to colorless sodium silicates. Thus, the white material has a smaller surface area and is slightly basic when compared with the pink material. Pink supports are relatively hard, have a high packing density, large surface area, and high loading capacity. They are used in both analytical and preparative-scale gas chromatography. White supports are more friable, less dense, have a smaller surface area and loading capacity, and are used in analytical gas chromatography. For analytical separations a support with a mesh range of 80–100 (149–177 µm) or 100–120 (125–149 µm) is a reasonable compromise between column performance and permeability.

Undesirable chromatographic properties, such as tailing, adsorption, and decomposition, are associated with the presence of metallic impurities and silanol groups at the surface of the diatomaceous supports. Acid and/or base washing is used to remove metal impurities and silanization to cap surface silanol groups. Silanization changes the character of the support from hydrophilic to hydrophobic. Consequently, silanized supports are used primarily with low-polarity stationary phases. They are unsuitable for coating with polar stationary phases. The treatment undergone by the diatomaceous support is usually stated on the manufacturer's label, e.g., Chromosorb W-AW-DMCS indicates that the white support was acid-washed and silanized with dimethyldichlorosilane. Addition of small quantities of 'tailing reducers' is sometimes necessary for successful chromatography of strong acids and bases. Tailing reducers are coated onto the support in a similar manner to the stationary phase or with the stationary phase, and to be effective, they must be stronger

acids or bases than the compounds to be separated. Examples include potassium hydroxide and poly(ethyleneimine) for the separation of bases and phosphoric acid for the separation of acids.

Other support materials of minor importance include various fluorocarbon powders, glass beads, carbon, and dendrite salts. Fluorocarbon powders are used primarily for the separation of reactive compounds that would destroy or be destroyed by other materials. A low surface energy and electrostatic properties make fluorocarbon powders difficult to coat and pack into columns. Because of their controlled shape, glass beads are used mainly for theoretical studies but have a low loading capacity and an active surface.

### Coating and Packing Techniques

Supports are usually coated with the stationary phase by any of several evaporation methods. For example, the stationary phase in a suitable solvent is mixed with the support and the solvent gently evaporated while stirring in an open dish under a heat lamp or slowly evaporated under vacuum from a fluted flask attached to a rotary evaporator. The damp support is then air-dried, oven-dried, or dried in a fluidized bed dryer. The latter is recommended because it is faster and leads to more permeable and efficient packed columns by stripping away fines produced in the coating process. The dried packing is then added in small increments to an empty column with a glass wool plug at its exit and consolidated with the aid of suction and gentle vibration. By convention, packings are prepared on a weight per weight basis and quoted as percent liquid phase. Typical phase loadings vary from 0.5% to 30% w/w depending upon the intended use for the column.

Stainless steel, nickel, or glass tubes bent into various shapes to fit the column oven of the gas chromatograph provide the container for the packings. Nickel (after acid passivation) and glass are the most inert column materials, and are preferred for the separation of labile compounds. Teflon or plastic tubing is also used occasionally, often for the separation of reactive compounds for which fluorocarbon powder supports are also required.

## Stationary Phases

Over the years thousands of substances have been used as stationary phases. For several reasons most of these have been abandoned in favor of a small number of liquids and adsorbents with favorable thermal stability and kinetic properties, complementary selectivity, reasonably well-defined and reproducible chemical composition, and if used in WCOT columns, the possibility of immobilization. Practical considerations dictate that liquid stationary phases should be inert, of low vapor pressure, have good coating characteristics, and have reasonable solubility in some common volatile organic solvent. The desirability of a wide temperature operating range tends to dictate that most common stationary phases are polymeric materials, although polymers are more likely to show greater composition variation than stoichiometric compounds.

Common liquid phases belong to one or other of the categories: (1) hydrocarbon and perfluorocarbon liquids, (2) ether and ester liquids, (3) ionic liquids, and (4) poly(siloxanes). Of these, poly(siloxanes) and poly(ethylene glycol) stationary phases dominate the practice of WCOT columns, because unlike most liquids they can be immobilized by simple chemical reactions to prepare films of different thickness that are stable to temperature variation and solvent rinsing while retaining favorable kinetic properties.

Some representative examples of packed column stationary phases belonging to categories (1)–(3) are summarized in Table 4. Hydrocarbons are used as low-selectivity liquid phases for separations of (mainly) low-polarity compounds by differences in their vapor pressure. Highly fluorinated liquid phases

are used for the speciation of fluorocarbon compounds or the separation of reactive compounds such as metal fluorides, interhalogen compounds, and nonmetal halides that tend to destroy conventional phases. The meta-linked poly(phenyl ethers) with five or six rings are weakly selective stationary phases with a defined chemical structure of exceptionally low volatility for their molecular weight. The term poly(ester) is used to describe a wide range of resinous composites derived from the reaction of a polybasic acid with a polyhydric alcohol. The most frequently used poly(ester) phases are the succinate and adipate esters of ethylene glycol, diethylene glycol, and butanediol. These phases provide high selectivity for the separation of polar compounds but have been replaced in many of their former applications by the more stable poly(cyanoalkylsiloxanes). Thermal-induced changes in composition, susceptibility to degradation by oxygen and water at elevated temperatures, and reaction with some polar compounds have contributed to their diminished use in recent years. The poly(ethylene glycols) are popular general-purpose liquid phases for the separation of volatile polar compounds. The poly(ethylene glycol) Carbowax 20M is one of the most popular phases for packed column gas chromatography, and in a modified form, is widely used for separations by WCOT columns. Ionic liquids are novel solvents composed entirely of ions. Those used for gas chromatography are alkylammonium, alkylphosphonium, or 1,3-dialkylimidazolium salts with weak nucleophilic anions such as sulfonates or tetrafluoroborate. These anions promote high thermal stability affording adequate liquid ranges for separation

**Table 4** Characteristic properties of some packed column liquid phases

Name and structure	Temperature range (°C)	
	Minimum	Maximum
Squalane 2,6,10,15,19,23-hexamethyltetracosane	<20	120

purposes. Their separation characteristics are complementary to polar nonionic liquid phases.

### Poly(siloxane) Liquid Phases

The poly(siloxanes) are the most popular stationary phases for both WCOT and packed column gas chromatography. Favorable features include: a wide temperature operating range; acceptable diffusion and solubility characteristics for different solute types; chemical inertness; good film forming properties; ease of synthesis with a wide range of chromatographic selectivity; and ease of immobilization for applications employing WCOT columns. The poly(siloxanes) used in gas chromatography are generally linear polymers of the type shown in **Figure 2**, in which the R group can be a number of different substituents such as alkyl, vinyl, phenyl, 3,3,3-trifluoropropyl, or 3-cyanopropyl. By varying the identity and relative amount of each R group as well as the ratio of monomer units, polymers with a wide range of solvent properties can be prepared.

The gradual evolution of column technology revealed that the low-to-medium viscosity poly(siloxane) oils preferred as packed column stationary phases (**Table 5**) were unsuitable for preparing WCOT columns of high thermal stability. Gum phases of generally higher molecular weight and viscosity are required for the preparation of WCOT columns with stable films resistant to disruption at elevated temperatures. The realization that cross-linking of gum phases to form a rubber affords a means of further stabilizing the poly(siloxane) films

without destroying their favorable diffusion characteristics was a further important breakthrough in WCOT column technology.

	Di(3-Cyanopropyl)siloxane			50	250

Two approaches are commonly used to immobilize poly(siloxanes) for the preparation of WCOT columns. These methods are: (1) thermal immobilization of silanol-terminated nonpolar and moderately polar poly(siloxanes) and (2) radical initiated cross-linking of endcapped poly(siloxanes) of a wider polarity range. Thermal induced reactions result in simultaneous bonding of the polymer to the column wall and the formation of cross-links between polymer chains. The use of silanol-terminated poly(siloxanes) was instrumental in the development of columns for high-temperature gas chromatography (Table 6). Free radical cross-linking of poly(siloxanes) requires the presence of a suitable catalyst (peroxide, azo-compound, or  $\gamma$ -radiation) as a free radical generator. In this case, cross-linking occurs through the formation of carbon-carbon bonds involving the organic substituents on neighboring poly(siloxane) chains. Only a low level of cross-linking (0.1–1%) is required for adequate immobilization. Increasing substitution of methyl groups by bulkier and/or polar substituents along the polymer backbone decreases the efficiency of radical cross-linking. For this reason, moderately polar poly(siloxane) stationary phases are synthesized with small amounts of vinyl, tolyl, or octyl groups attached to the siloxane backbone or as endcapping groups to increase the success of the cross-linking reaction. Even so, for poly(siloxanes) with a high percentage of polar monomers, immobilization may be incomplete and these phases are generally referred to as ‘stabilized’ in the trade literature. Stabilized columns usually have greater thermal stability than physically coated columns but are not resistant to solvent rinsing or as durable as columns containing immobilized stationary phases.

Another general advantage of immobilization is that it enables thick-film columns to be prepared to optimize the phase ratio for different applications. It is difficult to prepare conventionally coated columns with films thicker than  $\sim 0.5\ \mu\text{m}$ . Immobilized films of 1–8  $\mu\text{m}$  are easily prepared using cross-linking reactions.

The thermal stability of the poly(siloxanes) is enhanced by inserting phenyl groups (silarylene copolymers) or carborane groups into the polymer backbone (see Figure 2). Thermal degradation of poly(siloxanes) occurs by release of small ring cyclic siloxanes. These are formed in an intramolecular displacement reaction in which the silanol end group attacks a silicon atom in the same chain releasing the cyclic siloxane and forming a new silanol group. Incorporating phenyl or carborane groups in the polymer backbone inhibits this process by reducing the flexibility of the polymer chains. In addition, alternate and symmetrical substitution on the polymer backbone results in poly(siloxanes) of higher thermal stability.

## Classification of Liquid Phases

Various scales of solvent strength (polarity) and selectivity have been used to classify stationary phases. Classification based on polarity had to be abandoned because of the lack of a working definition. There is no substance that is uniquely polar and suitable to probe the polarity of other substances. Selectivity is defined as the relative capacity of a stationary phase for specific intermolecular interactions, such as dispersion, induction, orientation, and hydrogen-bond formation. Early attempts at a systematic definition of selectivity scales were based on the system of phase constants introduced by Rohrschneider and

**Table 6** Guide to the temperature operating range for bonded poly(siloxane) phases in WCOT columns

Type	Temperature range ( $^{\circ}\text{C}$ )		High-temperature version
	Minimum	Maximum	
Dimethylsiloxane	–60	325	420
Dimethyldiphenylsiloxane (5% diphenyl)	–60	325	420
Dimethyldiphenylsiloxane (35% diphenyl)	40	300	340

FFAP	40	250	

subsequently modified by McReynolds. McReynolds' phase constants are still indicated by many column manufacturers but are not a useful guide for column selection. Modern approaches to stationary phase classification by selectivity ranking are based on the cavity model of solvation. This model assumes that the transfer of a solute from the gas phase to solution in the stationary phase involves three steps. Initially, a cavity is formed in the stationary phase of the same size as the solute. The solute is then transferred to the cavity with reorganization of solvent molecules around the cavity and setup of solute-solvent interactions. In gas-liquid chromatography retention will depend on the cohesive energy of the stationary phase, represented by the free energy required for cavity formation, the formation of additional dispersion interactions of a solute-solvent type, and on selective solute-solvent polar interactions dependent on the complementary character of the polar properties of the solute and stationary phase. Quantitatively these interactions are described by the solvation parameter model set out below in the form suitable for gas-liquid chromatography:

$$SP = c + eE + sS + aA + bB + lL \quad [1]$$

where SP is the retention factor,  $\log k$ , or the gas-liquid partition coefficient,  $\log K_L$ . The remainder of the equations is made up of product terms called system constants ( $e$ ,  $s$ ,  $a$ ,  $b$ ,  $l$ ) and solute descriptors ( $E$ ,  $S$ ,  $A$ ,  $B$ ,  $L$ ). Each product term represents a contribution from a defined intermolecular interaction to the solute property. The solute descriptors are known for ~4000 compounds with others available by estimation or from experiment. They are not of immediate interest to us here. The system constants contain the information of the stationary phase properties and provide an unambiguous means of classification. The  $e$  system constant refers to the ability of the stationary phase to interact with solute  $n$ - or  $\pi$ -electron pairs. The  $s$  system constant to the ability of the stationary phase to take part in dipole-type interactions. The  $a$  system constant is a measure of stationary phase hydrogen-bond basicity and the  $b$  system constant a measure of stationary phase hydrogen-bond acidity. The  $l$  system constant (in part) describes the contribution of cavity formation and dispersion interactions to retention and more specifically the ability of the stationary phase to separate members of a homologous series. The phase constants for any stationary phase can be determined through the method of multiple linear regression analysis by measurement of a retention property for a series of varied solutes with known solute descriptors.

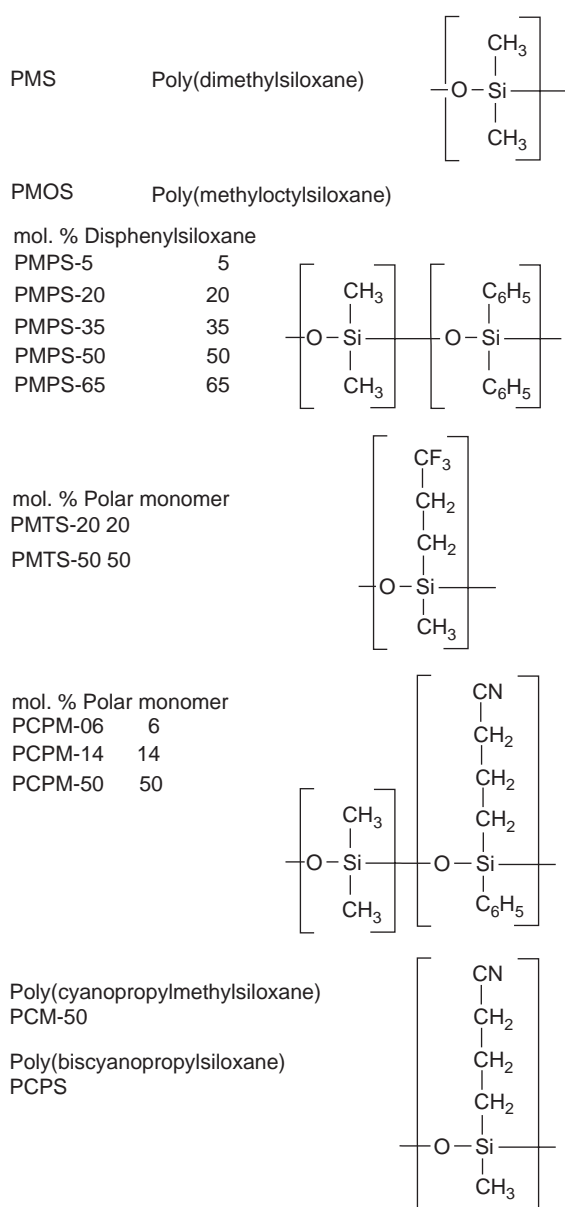

The system constants for a wide range of WCOT columns are summarized in Table 7 (this is part of a larger database containing systems constants at temperatures of 60°C, 80°C, 100°C, 120°C, and 140°C). The system constants are only loosely scaled to each other. Consequently, changes in magnitude in any column of Table 7 can be read directly, but changes in magnitude along rows must be interpreted more cautiously. Of immediate note is that none of the stationary phases are hydrogen-bond acids, and this interaction is, therefore, unimportant for classification of WCOT column stationary phases. The poly(siloxane) stationary phases (Figure 3) span a wide selectivity range. The poly(dialkylsiloxane) stationary phases are the least selective of the poly(siloxane) stationary phases, although compared to typical hydrocarbon phases, they possess a significant capacity for dipole-type and hydrogen-bond base interactions. Attempts to explain their separation characteristics based on nonselective interactions alone should be seen as an oversimplification. The incorporation of diphenylsiloxane monomer groups into the poly(dimethylsiloxane) backbone primarily increases the dipolarity/polarizability of the stationary phase with a small change in hydrogen-bond basicity and cohesion. The system constants change approximately linearly with composition up to ~50% diphenylsiloxane monomer and nonlinearly thereafter. The incorporation of 3,3,3-trifluoropropylmethylsiloxane monomer groups into the poly(dimethylsiloxane) backbone causes a significant change in the dipolarity/polarizability of the stationary phase with little alteration of the hydrogen-bond basicity. This results in a unique change in the  $s/a$  system constant ratio compared with other poly(siloxane) phases. These phases are also electron repulsive (negative  $e$  system constant) resulting from the presence of highly electronegative fluorine atoms. The incorporation of monomers containing cyanoalkyl groups into the poly(dimethylsiloxane) backbone increases the capacity of the poly(siloxanes) for dipole-type interactions as well as hydrogen-bond basicity. This results in a different range of  $s/a$  system constant ratios and a different selectivity to poly(siloxanes) containing 3,3,3-trifluoropropylmethylsiloxane monomer groups. For all poly(dimethylsiloxanes), incorporation of monomer groups containing polar functional groups results in an increase in the cohesion of the stationary phase, reflected in a smaller value for the  $l$  system constant. The poly(ethylene glycol) stationary phases complement the selectivity of poly(siloxane) stationary phases. They are the most hydrogen-bond basic of the stationary phases in Table 7 and have a significant capacity for dipole-type interactions. In

**Figure 3** Structures and general abbreviations for WCOT column stationary phases.

addition, they also possess a significant capacity for electron lone pair interactions.

The system constants for packed column stationary phases are summarized in **Table 8**. Classification of their properties by cluster analysis results in the connection dendrogram shown in **Figure 4**. Stationary phases with similar solvation properties are located next to each other and connected close to the left-hand side of the dendrogram. Stationary phases with no paired descendents are singular phases with properties that cannot be duplicated by other phases from the data set (**Table 8**). Classification results in six groups with three phases behaving

independently. Group one contains squalane, Apolane-87, OV-3, OV-7, SE-30, and OV-105. These are phases of low cohesive energy with minimal capacity for polar interactions. The second group contains OV-22, OV-25, OV-11, OV-17, PPE-5, and DDP. These phases have low cohesive energy and are weakly dipolar and hydrogen-bond basic. QF-1 is loosely connected to this group but is significantly more dipolar and electron lone pair repulsive. The third group contains OV-330 and OV-225 with UH50B loosely connected to this group. Compared with the second group, these stationary phases are more dipolar and hydrogen-bond basic and slightly more cohesive. They represent an increase in the intensity of the same range of interactions as the larger group two of stationary phases. The fourth group contains H10 and PSF6 (**Figure 5**). These are strong hydrogen-bond acid stationary phases but in other respects quite different to each other. The fifth group contains the ionic liquids. Stationary phases in this group are significantly dipolar/polarizable and the strongest hydrogen-bond bases. The sixth group of stationary phases is divided into two subgroups. TCEP and OV-275 are strongly dipolar/polarizable, hydrogen-bond basic, and have high cohesive energy. EGAD, CW20M, and DEGS have a similar range of polar interactions, but not quite as intense, and have a lower cohesive energy than TCEP and OV-275. These phases are also weakly hydrogen-bond acidic but it is likely that this is an artifact due to alteration of the structure of the stationary phases during use.

## Liquid-Crystalline Stationary Phases

Liquid-crystalline stationary phases are used for the separation of positional and geometric isomers of rigid molecules. Liquid crystals exhibit the mechanical properties of a liquid while retaining some of the anisotropic properties of the solid state. This preservation of order permits shape selectivity, while the liquid properties result in acceptable chromatographic efficiency. Several hundred liquid-crystalline phases of different chemical types have been used in packed column gas chromatography. They all have in common a markedly elongated, rigid, rod-like structure, and generally have polar terminal groups. The most common types are Schiff bases, esters, azo, and azoxy compounds. Most of these materials provide limited opportunities for use in WCOT columns because of poor column efficiency, poor coating characteristics, poor thermal stability, high column bleed, and limited temperature operating ranges. These shortcomings were largely overcome by the development of side-chain liquid-crystalline poly

(siloxane) phases. The biphenylcarboxylate ester poly(siloxane) (**Figure 6**) is the most widely used liquid-crystalline stationary phase for WCOT columns. It can be immobilized by standard methods, and has a useful temperature range from about 100°C to 250°C.

## Chiral Stationary Phases

The development of amino acid ester, dipeptide, and diamide chiral stationary phases provided the first indication that enantiomers could be separated by gas chromatography on stationary phases designed to promote multiple simultaneous interactions with an enantiomer. Real interest and progress in chiral separations resulted from the preparation of diamide

phases, grafted onto a poly(siloxane) backbone, suitable for coating on WCOT columns. The only commercially available example of this class of chiral selector is the poly(methylsiloxane) phase containing L-valine-*t*-butylamide (Chirasil-Val) (**Figure 7**), which permitted for the first time, a single separation of all the enantiomers of the common protein amino acids after derivatization.

## Cyclodextrin Derivatives

Initial attempts to use cyclodextrins and their derivatives as chiral stationary phases in gas chromatography met with limited success owing to their unfavorable melting points or decomposition

**Figure 4** Nearest neighbor complete link cluster dendrogram for the stationary phases in **Table 8**.

**Figure 5** Structures of the hydrogen-bond acid stationary phases H10 (A) and PSF6 (B).

temperatures. This changed with the discovery that some peralkylated derivatives (e.g., pentyl), partially alkylated derivatives, and mixed alkylated and acylated derivatives were viscous liquids that could be coated on deactivated glass surfaces (**Table 9**). Some 85% of enantiomers separated by gas

**Figure 6** Structure of the SB-smectic side-chain liquid-crystal line stationary phase (R is ~50% liquid crystal substituents).

**Figure 7** Structure of Chirasil-Val.

chromatography on derivatized cyclodextrins can be separated on one of three derivatized cyclodextrins: octakis(3-*O*-trifluoroacetyl-2,6-di-*O*-*n*-pentyl)- $\gamma$ -cyclodextrin; heptakis(2,6-di-*O*-methyl)- $\beta$ -cyclodextrin; and heptakis(2,6-di-*O*-*n*-pentyl)- $\beta$ -cyclodextrin. Octakis(3-*O*-butyryl-2,6-di-*O*-*n*-pentyl)- $\gamma$ -cyclodextrin also has a broad application range. It is generally accepted that enantioselectivity results from either inclusion formation and/or surface interactions controlled by the structure of the cyclodextrin derivatives. So far no simple method has emerged to identify the optimum stationary phase for a separation from enantiomer structure.

The general use of cyclodextrin derivatives as stationary phases has declined in recent years in favor of cyclodextrin derivatives either dissolved in, or chemically bonded to, a poly(siloxane) stationary phase. These phases possess higher thermal and mechanical stability, as well as higher efficiency. A wider range of cyclodextrin derivatives can be employed, since melting point and phase transition are no longer considerations for solutions (**Table 9**). The cyclodextrin derivatives are typically dissolved in moderately polar poly(siloxane) stationary phases at a concentration of 5–50% (w/w). The  $\alpha$ - and  $\beta$ -cyclodextrins with 6-*O*-*t*-butyldimethylsilyl ether (or 6-*O*-*t*-hexyldimethylsilyl ether) groups with methyl or acetyl groups at C-2 and C-3 are among the most effective cyclodextrin derivatives for the separation of different enantiomer types.

Improvements in column stability were achieved by grafting the cyclodextrin derivative onto the

<sup>a</sup> Highest temperature (°C) for isothermal operation.<sup>b</sup> Most common poly(siloxane) solvents are poly(cyanopropylphenyldimethylsiloxane) with 14% cyanopropylphenylsiloxane monomer or poly(dimethyldiphenylsiloxane) with 20–35% diphenylsiloxane monomer. Mixing ratio for the cyclodextrin derivative is 5–50% (w/w).

backbone of a poly(dimethylsiloxane) polymer suitable for thermal immobilization (Figure 8). Several columns of this type are commercially available (e.g., heptakis(2,3,6-tri-*O*-methyl)- $\beta$ -cyclodextrin

**Figure 8** Structures of immobilized poly(siloxane) chiral stationary phases containing (A) a cyclodextrin derivative (Chirasil-Dex) and (B) a metal complex (Chirasil-Nickel).

(Chirasil-Dex), heptakis(3-*O*-trifluoroacetyl-2,6-di-*O-n*-pentyl)- $\beta$ -cyclodextrin, and octakis(3-*O*-butyl-2,6-di-*O-n*-pentyl)- $\gamma$ -cyclodextrin (Chirasil- $\gamma$ -Dex)), although columns containing dissolved selectors remain the most widely used.

Cyclodextrin derivatives have been spectacularly successful in separating a wide range of low molecular mass enantiomers of different types that are difficult or impossible to separate by other means.

### Metal Complexes

Metal(II) bis[3-(trifluoroacetyl)-(1*R*)-camphorate] and bis[3-(heptafluorobutanoyl)-(1*R*)-camphorate] of nickel, cobalt, and manganese dissolved in a noncoordinating solvent, such as poly(dimethylsiloxane), or grafted onto the backbone of a poly(dimethylsiloxane) (Figure 8) are highly selective stationary phases for the separation of a variety of stereoisomers that includes hydrocarbons and oxygen-, nitrogen-, and sulfur-containing electron-donor analytes by gas chromatography. Selectivity results from the difference in stability constants for the fast and reversible chemical equilibrium between the metal coordination compound and analytes. Thermal instability of the coordination complexes, and small stability constants at higher temperatures, restrict separations to volatile compounds that can be separated at temperatures below 125°C.

### Solid Stationary Phases

Gas-solid chromatography is used for a narrower range of separations than gas-liquid chromatography. Because of higher retention, typical applications are the separation of fixed gases, volatile hydrocarbons, halocarbons, organic solvents, and sulfur gases. The presence of immobilized active centers enhances the separation of isomers and isotopes.

**Table 10** Characteristic properties of porous polymer beads for packed column gas chromatography

Porous polymer	Monomers	Surface area ( $\text{m}^2 \text{g}^{-1}$ )	Average pore diameter (mm)	Temperature limit ( $^{\circ}\text{C}$ )
Chromosorb 101	STY-DVB	30–40	300–400	275
Chromosorb 102	STY-DVB	300–400	8.5–9.5	250
Chromosorb 103	STY	15–25	300–400	275
Chromosorb 104	ACN-DVB	100–200	60–80	250
Chromosorb 105	Polyaromatic	600–700	40–60	250
Chromosorb 106	STY	700–800	5	225
Chromosorb 107	Acrylic ester	400–500	8–9	225
Chromosorb 108	Acrylic ester	100–200	25	225
Porapak N	STY-DVB-VPO	225–500	9	200
Porapak P	STY-DVB-EVB	100–200	7.5–10	250
Porapak Q	EVB-DVB	500–850	7.5–10	250
Porapak R	STY-DVB-VPO	450–600	7.5–10	250
Porapak S	STY-DVB-VP	300–550	7–9	250
Porapak T	EGDMA	250–450	9	200
Porapak PS	Silanized P			
Porapak QS	Silanized Q			250
Tenax-GC	DPO	19–30	25–7500	375

Values for surface area vary widely in the literature.

STY, styrene; DVB, divinylbenzene; ACN, acrylonitrile; EVB, ethylvinylbenzene; EGDMA, ethylene glycol dimethacrylate; VPO, vinylpyrrolidone; VP, vinylpyridine; DPO, 2,6-diphenyl-*p*-phenylene oxide.

These separations are often difficult or impossible with liquid phases. A general guide to the selection of sorbents for particular applications is given in Table 10. PLOT columns provide higher efficiency, faster separations, and faster column regeneration compared with packed columns. PLOT columns, however, are generally less efficient than WCOT columns and have a limited sample capacity. The carrier gas competes with the analyte for interactions at the stationary phase and thus the choice and average column pressure of the carrier gas can affect selectivity.

Modern PLOT columns are prepared either by *in situ* polymerization or by addition of a chemical binder to the coating solution resulting in immobilization and bonding of particles to the inside column wall. PLOT columns containing immobilized layers of inorganic oxides, carbon, molecular sieves, cyclodextrins, and porous polymers are available in lengths up to 100 m with internal diameters from 0.25 to 0.53 mm and layers of 5–50  $\mu\text{m}$  thickness.

### Inorganic Oxides

The most important inorganic oxide adsorbents are silica gel and alumina. These adsorbents are available in a wide range of particle sizes and morphology. For packed columns, rigid spherical beads with surface areas in the range 5–500  $\text{m}^2 \text{g}^{-1}$  and average pore diameters from 8–150 nm are generally used. Similar porous materials of a smaller average particle size less than 10  $\mu\text{m}$  are used for the preparation of PLOT columns. Retention is a function of the specific

surface area, the degree of surface contamination (by water in particular), the prior thermal conditioning of the adsorbent, and the ability of the solute to participate in specific interactions, such as hydrogen bonding, with surface functional groups. The different surface functional groups (silanol groups in the case of silica and aluminum ions in the case of alumina) results in different selectivity for these adsorbents. Coating the adsorbent with a small quantity of an involatile liquid (usually a common stationary phase) or an inorganic salt is used to modify selectivity and improve efficiency. Alkali metal salts (potassium chloride and carbonate, sodium sulfate, etc) at loadings of 0.5–30% w/w are common salt modifiers.

### Carbon

Active carbons are rarely used in gas chromatography because of the difficulty in standardizing their activity and morphological properties. Graphitized carbon blacks and carbon molecular sieves have largely superseded them. Graphitized carbon blacks are prepared by heating ordinary carbon blacks to  $\sim 3000^{\circ}\text{C}$  in an inert atmosphere. This high-temperature treatment destroys functional groups originally present on the carbon surface and induces the growth of graphite crystallites. Graphitized carbon blacks used in gas chromatography are generally nonporous materials with surface areas from  $\sim 5$  to 100  $\text{m}^2 \text{g}^{-1}$ . Ideally, they should behave as nonspecific adsorbents with retention dominated by dispersion interactions. In reality, residual polar adsorption sites, albeit few

in number, establish strong specific interactions with polar solutes and affect selectivity and sample capacity. Modification of the surface by the addition of small quantities of polar liquids is used to adjust selectivity and to minimize peak tailing. PLOT columns prepared from carbon molecular sieves are more widely used today.

### Molecular Sieves

Carbon molecular sieves are prepared by the controlled pyrolysis of poly(vinylidene chloride) or sulfonated polymers (Carboxen<sup>TM</sup>). They consist of very small graphite crystallites cross-linked to yield a disordered cavity-aperture structure. Carbon molecular sieves are microporous and of high surface area, 200–1200 m<sup>2</sup> g<sup>-1</sup>. They are used primarily for the separation of inorganic gases, C<sub>1</sub>–C<sub>3</sub> hydrocarbons, and for the separation of small polar molecules such as water, formaldehyde, and hydrogen sulfide. Less volatile compounds cannot be desorbed efficiently at acceptable temperatures.

Molecular sieves (zeolites) are artificially prepared alkali metal aluminosilicates. Those used for gas chromatography are type 5A, a calcium aluminosilicate with an effective pore diameter of 0.5 nm, and type 13X, a sodium aluminosilicate with an effective pore diameter of 1 nm. The molecular sieves are microporous with a tunnel-like pore structure of similar dimensions to those of small molecules. Retention is primarily governed by the size of the analyte, which determines whether it can enter the pore structure of the molecular sieve, and the strength of adsorption interactions that take place on the internal pore surface. Molecular sieves are used primarily for the separation of permanent gases (hydrogen, oxygen, nitrogen, carbon monoxide, and the inert gases) and low molecular weight linear- and branched-chain hydrocarbons. Water, carbon dioxide, and other polar molecules are retained excessively and catalytic transformations of labile analytes are also common.

### Porous Polymers

Uniform porous polymer beads, sufficiently rigid to be dry packed into a column, are simply prepared from different monomers by suspension polymerization (Table 10). For the preparation of PLOT columns the polymerization is performed in the column followed by a second step in which the particles are immobilized onto the inside column wall. The properties of the polymers vary with the choice of

monomers, the pore structure, and the surface area. Porous polymers with average pore diameters less than 10 nm are used primarily for the separation of gases while those with larger pore diameters are used for the separation of low molecular weight organic compounds. Compared with other common sorbents their surfaces are relatively inert, and polar compounds such as water, formaldehyde, carboxylic acids, and alkylamines can be separated without appreciable difficulty.

Tenax-GC is a linear polymer of *p*-2,6-diphenylphenylene oxide with a molecular weight of about one million. It is a granulated powder of low surface area with remarkable thermal stability. This allows applications at isothermal temperatures up to 375°C.

## Gas-Solid Chromatography

### Introduction

Gas chromatography is one of the major analytical methods; it is used in various branches of industry (petrochemical, chemical, gas industry, etc.), in pharmaceuticals, in the control of environmental pollution, in medicine, in agriculture, and in scientific research.

Chromatographic techniques are often classified according to the physical state of the two (moving and stationary) phases used. Accordingly, the following terms are in use for gas chromatography: gas-solid chromatography (GSC) and gas-liquid chromatography (GLC). Often, a classification is based on the mechanism of retention of compounds to be separated. In 'adsorption' chromatography separation is based mainly on differences between the adsorption affinities of the sample components for the surface of an active solid. Strictly speaking, gas adsorption chromatography (GAC) can also be performed in the framework of GLC, for example, if the chromatographed substances are practically insoluble in the stationary liquid phase (for example, water in poly(dimethylsiloxane) and hydrocarbons in polar liquid phases (for example, diglycerol,  $\beta\beta'$ -thiodipropionitrile)). In these examples, the retention is primarily due to adsorption of the sorbate on the gas-stationary liquid phase interface. Very often the mechanism of retention in gas chromatography is mixed (i.e., adsorption-absorption).

Schuftan was, probably, the first to suggest GAC. Important contributions to this variant of chromatography are due to Hesse.

The contributions of Cramer, Janak, Kiselev, and Yashin are notable in the initial development of GAC. Capillary gas-adsorption columns were widely used during the last 10–15 years.

### Special Features of GAC

The widespread use of GSC is explained by the following main advantages of this variant of chromatography:

1. Enhanced selectivity and sorption capacity of adsorbents, which make it possible to separate

organic or inorganic compounds having similar physicochemical properties. Examples include the separation of inorganic and organic compounds on molecular sieves, graphitized carbon black, or organic polymeric adsorbents.

2. The higher efficiency of separation compared with GLC, which is due to the fact that mass exchange processes occur more rapidly.
3. The high thermal stability of adsorbents.
4. The possibility of separating of gases and volatile compounds at 40–50°C using conventional gas chromatographs without special cooling.
5. The lower detector 'noise' due to the fact that the adsorbents are usually nonvolatile.

The unique features of GAC have also attracted the attention of Giddings: 'One immediate advantage of gas-solid chromatography resides in the fact that a surface coated with any reasonable degree of uniformity will exhibit a coefficient of resistance to mass transfer substantially smaller than the corresponding coefficient for a liquid adsorption layer in gas-liquid chromatography. The second immediate advantage of gas-solid chromatography resides in the great potential selectivity of the adsorption process. Surface adsorption is potentially capable of offering the most versatile and selective characteristics of any of the known retentive mechanisms. The rigidly fixed forces of a solid surface contrast sharply with the fluid forces of a liquid phase.'

Of course, GSC is not free of drawbacks. These include the following:

1. Poor reproducibility of sorption and chromatographic characteristics of adsorbents used (compared with those of liquid phases).
2. Asymmetry of chromatographic zones resulting from nonlinearity of adsorption isotherms.
3. A higher probability (compared with that in GLC) of irreversible adsorption and catalytic transformations of the compounds being analyzed on the surface of an adsorbent.
4. The restricted range of available adsorbents for GSC.

Of the above drawbacks the most important is the asymmetry of analytical zones, which usually results from the presence on the adsorbent surface of a number of active adsorption centers. The most efficient method of 'straightening' the adsorption isotherm lies in the modification of solid adsorbents with small amounts of polar nonvolatile liquids,

which predominantly 'deactivate' most active adsorption centers.

Comparing the advantages and drawbacks of GAC shows that the advantages of this variant are much more significant than its drawbacks. This is also supported by the fact that columns with such adsorbents as alumina, silica, graphitized carbon black, molecular sieves, and organic polymers are widely used.

The advantages of GAC can be fully utilized by using its capillary variant.

## Retention of Compounds in GSC

Retention in GSC is determined both by the nature of the surface of the adsorbent and by its structure. It has been shown that the net retention volume,  $V_N$ , is directly proportional to the surface area ( $S_{ad}$ ) of the adsorbent (it has been assumed that at relatively low coverages, the accessibility of the adsorbent surface does not change):

$$V_N = K_s S_{ad}$$

where  $K_s$  is the coefficient of distribution of the substance subjected to chromatography between the adsorbent surface and the gas phase.

Note an important specific feature of GSC, namely that the retention of compounds depends on the nature of the mobile phase. The replacement of light carrier gases by heavy gases leads to dynamic modification of the adsorbent surface, to a decrease in the coefficients of distribution of the compounds being analyzed in the 'solid adsorbent-gas' system, and, hence, to a decrease in retention times.

As in other variants of chromatography, the retention values used most in GSC are not absolute but relative (retention factor,  $k$ , relative retention,  $r$ , and Kovats retention index,  $I$ ), characterized by a higher reproducibility than that of absolute retention values.

As has been shown in the last ten years, relative retention values depend both on the nature of the carrier gas adsorbent (stationary phase) and chromatographed sorbate used and on its average pressure,  $P_{av}$ , in the column. Here nature is complex of properties, which characterize chemical substance or their mixture.

With relatively small pressures ( $P_{av}$  lower than 5–10 atm), relative retention values are linear functions of the average pressure,  $P_{av}$ , of the carrier gas in the column and its identity. For example, the following equation is valid for the retention index,  $I_i(P)$ :

$$I_i(P_{av}) = I_{0i}(0) + b_{li}P_{av}$$

where  $I_{0i}$  is the limit value of the retention index of the  $i$ th chromatographed compound when  $P_{av}$  tends

to zero, and  $b_{li}$  is the adsorption coefficient, depending on the adsorbent-carrier gas system.

## Zone Broadening in Capillary Gas Adsorption Columns

Zone broadening during migration along the column is influenced by the flow profile of the carrier gas in the column, by the diffusion of the substances being separated in mobile and stationary phases, by the rate of interfacial mass transfer, and by the characteristics of the adsorption layer used.

An equation relating the height equivalent to a theoretical plate (HETP) to the linear velocity of the carrier gas for GAC was proposed by Giddings. The Giddings equation can be represented as

$$H = \frac{2D_g}{u_o} + \left[ \frac{1 + 6k + 11k^2}{24(1 + k)^2} \right] \frac{r^2 u}{D_g} f_1 + \frac{8}{a_k u_m} \left( \frac{k}{k + 1} \right)^2 \frac{V_g}{S} f_n u_o f_2$$

where  $H$  is the HETP;  $D_g$  is the diffusion coefficient of the compound under analysis in the gas phase;  $u$  is the linear velocity of the carrier gas;  $k$  is the retention factor; and  $V_g$  is the specific retention volume.  $u_o$  is the linear velocity of the carrier gas at the outlet of the column:

$$u_o = \frac{L}{t_m f_2}$$

where  $L$  is the length of the column; and  $t_m$  is the 'dead time' of the column:

$$f_1 = \frac{9(P^4 - 1)(P^2 - 1)}{8(P^3 - 1)}$$

$$f_2 = \frac{3(P^2 - 1)}{2(P^3 - 1)}$$

where  $P = P_i/P_o$ ,  $P_i$  and  $P_o$  are the carrier-gas pressures at the inlet and outlet of the column, respectively;  $a_k$  is the accommodation coefficient;  $u_m$  is the average velocity of the sample in the gas phase;  $S$  is the overall surface area of the adsorbent layer in the column; and  $f_n$  is a factor reflecting the heterogeneity of the adsorbent.

## Preparation of Capillary Adsorption Columns

Only methods of preparation of capillary columns with a porous adsorbent layer are described in the

literature. This type of column is characterized by high capacity and stable performance.

Two methods are used for the preparation of capillary gas adsorption columns: the suspension method, in which the inner walls of the column are coated with a suspension of the adsorbent, and the chemical method, in which an adsorption layer is formed on the walls of the column through a process of synthesis of the adsorbent in the capillary column. Recently, a new type of porous polymer (poly(1-(trimethylsilyl)-1-propin) (PTMSP)) has been suggested as an organic adsorbent and has been actively studied as a promising material in membrane technology. This polymer dissolves well in some volatile solvents, and a layer of it can be formed in a capillary column using simple techniques for coating from a solution of a stationary phase in a volatile solvent.

## The Use of GSC

At present, GSC is widely used in analytical practice, and the capillary variant of GSC is used most effectively and most often. Considering the advantages of capillary columns over packed columns, only the higher efficiency of the former is often mentioned. At the same time, capillary columns are also characterized by faster separations, by more reproducible temperature regimes, by the small sizes of the apparatus needed, and by lower consumption of carrier gases and sorbents; they also extend applications to the lower temperatures.

At present, GAC is used most frequently for analysis of volatile compounds with various isotope compositions, of inorganic and organic gases, of volatile organic polar compounds, and of aqueous solutions of organic compounds.

The separation of nuclear spin isomers and isotopes of hydrogen was the first prominent example of a practical application of capillary adsorption chromatography (Figure 1). Later, it was shown that the time required for the separation of protium and deuterium could be shortened by decreasing the column temperature to 47 K.

Oxygen isotopes ( $^{16}\text{O}_2$  and  $^{18}\text{O}_2$ ) were separated by capillary adsorption chromatography (Figure 2). The adsorption layer on the inner wall of a glass column was produced by etching with 20% NaOH for several hours at 100°C. The efficiency of the capillary columns was  $\sim 350\,000$  theoretical plates. A mixture of nitrogen (65%) and helium (35%) was used as the carrier gas.

The use of porous polymers as adsorbents offers a number of advantages, among them the high

**Figure 1** Chromatogram of the separation of nuclear spin isomers and isotopes of hydrogen in an open tubular adsorption glass capillary column. The 80 m long open tubular capillary column contained a 20 mm thick silica layer as an adsorbent;  $T = 77.4\text{ K}$ ; neon was used as the carrier gas. 1, helium; 2, *p*-protium; 3, *o*-protium; 4, DH; 5, *o*-deuterium; 6, *p*-deuterium.

**Figure 2** Chromatogram of the separation of a mixture of the isotopes  $^{16}\text{O}_2$  and  $^{18}\text{O}_2$  in an adsorption glass capillary column (175 m  $\times$  0.3 mm) at 77 K, with a  $\text{N}_2(65\%)$ -He(35%) binary carrier gas.

homogeneity of the surface with controllable (within certain limits) porosity and hydrophobicity.

Note that natural organic adsorbents can also be used in capillary columns. Figure 3 shows the results of the separation of organic acids of natural origin on a natural polymer, *Staphylococcus aureus* cells. A fairly satisfactory degree of separation was achieved. The use of natural adsorbents seems promising.

Columns with traditional adsorbents, for example, graphitized carbon black, also find practical application. 'Structural sensitivity', which is manifested in the separation of isomers, is a specific feature of graphitized carbon black. This feature is illustrated by the separation of hydrocarbons (Figure 4). All three isomers of xylene are separated.

**Figure 3** Chromatogram of the separation of unsaturated acids in an open tubular capillary column in which *Staphylococcus aureus* cells were used as the adsorbent. Acids: 1, 14:1 tetradecenoic; 2, 14:0 myristic; 3, 15:0 pentadecanoic; 4,  $c\Delta^8$  16:1 *cis*-hexadec-8-enoic; 5,  $c\Delta^9$  16:1 *cis*-hexadec-9-enoic (palmitic); 6,  $c\Delta^{10}$  16:1 *cis*-hexadec-10-enoic; 7,  $c\Delta^{11}$  16:1 =  $t\Delta^9$  16:1 *cis*-hexadec-11-enoic and *trans*-hexadec-9-enoic; 8,  $t\Delta^{10}$  16:1 *trans*-hexadec-10-enoic; 9,  $t\Delta^{11}$  16:1 *trans*-hexadec-11-enoic; 10,  $t\Delta^{12}$  16:1 *trans*-hexadec-12-enoic; 11, 16:0 palmitic; 12,  $c\Delta$  17:0 *cis*-methylenehexadecanoic; 13,  $t\Delta$  17:0 *trans*-methylenehexadecanoic; 14, 18:0 octadecenoic; 15, 18:0 stearic.

**Figure 4** Chromatogram for the separation of a mixture of organic hydrocarbons in a capillary column with graphitized carbon black. 1, *n*-octane; 2, benzene; 3, *n*-nonane; 4, toluene; 5, *p*-xylene; 6, *m*-xylene; 7, *o*-xylene. A 30 m  $\times$  0.32 mm column with Carbowack B was used;  $T = 60^\circ\text{C}$ ; helium was used as the carrier gas.

The use of film-forming organic polymers, which are commonly used in membrane technology, as chromatographic adsorbents for packed and capillary columns has been suggested. It was shown that

**Figure 5** Chromatogram of a mixture of inorganic hydrides: 1,  $\text{SiH}_4$ ; 2,  $\text{H}_2\text{S}$ ; 3,  $\text{PH}_3$ ; 4,  $\text{GeH}_4$ ; 5,  $\text{AsH}_3$ . Experimental conditions: flame-photometric detector,  $\lambda = 394\text{ nm}$  (peak 2),  $\lambda = 525\text{ nm}$  (peaks 1, 3–5); quartz capillary column (25 m  $\times$  0.22 mm), adsorbent PTMSP (layer thickness 0.4  $\mu\text{m}$ ), column temperature  $100^\circ\text{C}$ , carrier gas helium (35  $\text{cm s}^{-1}$ ).

$\text{C}_1$ – $\text{C}_4$  hydrocarbon gases were separated on columns with a layer of PTMSP. This polymer is also promising for the separation of inorganic gases (Figure 5).

## Multidimensional Techniques

P J Marriott, RMIT University, Melbourne, VIC, Australia

### Introduction

The gas chromatographic (GC) technique dates from the 1950s. One of the earliest applications was the analysis of fatty acid methyl esters. It is recognized that in the decades since, almost every conceivable sample type containing volatile compounds has been subjected to GC analysis. Not only is the general application of GC to a vast array of samples of historical interest, but the modification of the method to provide better or optimum analysis of a given sample type has been a feature in the development of the GC method since its first demonstration. In this respect, it is the effective resolution (separation) of components of a sample that is the desired outcome. Quite simply, this will invariably mean that qualitative and quantitative analysis of samples is more reliable. Thus, in terms of better analysis we will almost always demand improved separation, because this is the essence of any chromatographic technique – to provide separation. This technological push is precisely why capillary GC, with its significantly greater peak capacity, has effectively replaced packed column GC for most routine analysis. Whilst there are other advantages pertaining to capillary GC, such as improved inertness, the consideration still is that even these factors are related to separation power and/or improved quantification.

Against this backdrop, it is recognized that even the highest separation power single capillary column method cannot achieve the analysis performance demanded to effectively separate to baseline all components of many complex samples. Statistically, once the number of compounds exceeds a certain level (e.g., ~20%) of the separation capacity of a column for randomly distributed components, then peak overlaps and reduced resolution of individual components arises. The separation capacity may be defined as the number of baseline-resolved components that can be fitted into the analysis separation space (i.e., how many peaks can be placed side-by-side in the chromatographic space; **Figure 1A**). For some multicomponent samples, such as a petroleum oil or product (e.g., kerosene), the vast majority of compounds will be unresolved (i.e., they will not be pure peaks). Major components such as *n*-alkanes may be readily recognized, but underlying these peaks will be other minor components. Depending on the degree

of accuracy required of the analysis, the co-eluting impurity may not be too critical, but for certainty of analysis, the presence of an unaccounted impurity leads to unacceptable results.

Presented with this scenario, and the need to provide greater analytical measurement certainty, there are a number of strategies that can be taken to improve analysis of individual components, and provide greater separation power. Accepting the limited capacity of the single column, these strategies will involve either making the sample mixture less complex, or making the GC step more efficient – which can only be achieved by using a suitable arrangement comprising more than one column. Since these involve more than one sample separation step, they can be collectively called multidimensional separations. Multidimensional separation may be considered to encompass a broader scope than multidimensional gas chromatography (MDGC). The former can incorporate a preseparation of a sample into fractions, each of which can then be separately analyzed by GC. If two components that would normally co-elute are now present in different analyzed fractions, then by definition they will be no longer unresolved. This approach has been widely employed in petroleum analysis, where such methods as thin layer chromatography or liquid chromatography are used to fractionate a crude sample, and each zone or class of compounds that are isolated into separate extracts are then analyzed by GC. High-performance liquid chromatography can be used in a like manner, whether offline or online coupled to the GC.

With respect to post-GC column procedures, there is limited scope for increasing the resolving power of the total analysis. It is essentially only possible to follow a GC step (dimension) with another GC dimension. This now defines the MDGC method (**Figure 1B**). Considering this to be described as using a GC step to further analyze or differentiate the effluent from a first GC column, then this can be contrasted to using a spectroscopic detection step to analyze GC effluent. This is important, because today it is widely believed that for unresolved GC peaks the only way to effectively, uniquely, measure the individual compounds is by spectroscopic means (e.g., mass spectrometry (MS)). Note that however it is more appropriate to term the latter multidimensional analysis, as opposed to multidimensional chromatographic separation. The conceptual difference between GC-MS and MDGC is illustrated in **Figure 2**. MDGC aims to separate peaks in two

**Figure 1** (A) Peak capacity ( $n_c$ ) expressed for a single GC column. (B) Peak capacity expressed for a multidimensional GC analysis, with a first-dimension GC column ( $n_c$ ) and one heartcut event to a second-dimension GC column capacity ( $m_c$ ). Total capacity  $\sim n_c + m_c$ . (C) Peak capacity expressed for a comprehensive two-dimensional GC analysis where each dimension has capacity  $n_c$  and  $m_c$ , respectively. Total capacity  $\sim n_c \times m_c$ .

dimensions, whereas GC–MS attempts to provide unique mass spectral ions to measure quantitatively and qualitatively peaks that might overlap.

Multidimensional gas chromatography may be defined as follows: ‘the process of selecting a (limited) region or zone of eluted compounds issuing from the end of one GC column, and subsequently subjecting the zone to a further GC displacement’.

Figure 3 shows how different regions (here two regions) from a first column (Figure 3A) can be selected and passed to a second column, where better separation occurs (Figure 3B). Mass spectrometric data will be a series of contiguous mass spectra (Figure 3C) acquired for the total GC run.

This process can be repeated as many times as required or as physically permitted by the technical

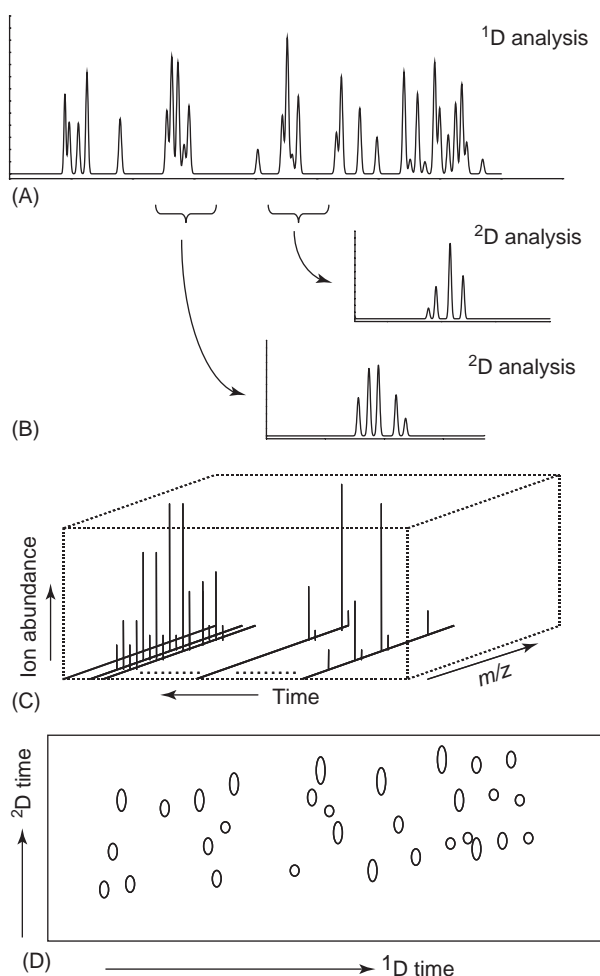

system employed. The selected zone may be chosen to enhance the separation of a particularly complex zone, which may be minutes broad, or it may be used to isolate just a few peaks of importance. The limiting example of this will be to select just ‘one’ peak from  $^1D$  and transfer it to  $^2D$ . This may seem a trivial example, but if the target peak is enantiomeric, and  $^2D$  is required to provide enantioseparation, then an enantioselective phase in  $^2D$  will achieve this: the goal is to isolate the ‘single peak’ and subsequently to resolve its enantiomers. If a single enantiomeric column is used for the total sample, then it may be that the resolved enantiomers will co-elute with other matrix peaks and so compromise the analysis.

Various generic arrangements of coupled column GC are shown in Figure 4. Some are trivial, such as

**Figure 2** Illustration of the difference between GC/MS and MDGC. Peaks elute from  $1^D$  at their characteristic  $1t_R$ , either into a second column (MDGC) where their resolution is improved through the use of a second column which provides differentiation in time (i.e.,  $2t_R$  values for each component) or into the MS source (GC–MS), where there is no differentiation in time, but characteristic  $m/z$  ions are produced for all peaks eluting from  $1^D$ . For unresolved peaks, either unique ions or spectral deconvolution is required for providing reliable analysis.

**Figure 4A**, which shows directly connected columns. Adding a midpoint pressure (**Figure 4B**) allows tuning of the overall phase selectivity, and whilst **Figure 4A** and **4B** may give better resolution, they are not strictly multidimensional. **Figure 4C** is the simplest representation of an MDGC arrangement, with a monitor detector and switching device to heartcut solute from  $1^D$  to  $2^D$ . Often a cryotrap will collect/focus selected heartcuts at the head of  $2^D$ . A multiple trap design (**Figure 4D**) permits collections of fractions of the  $1^D$  effluent independent of the need to analyze them on the second column. Using a flow switch device between the two columns, it is possible to perform a range of advanced modes, such as back-flushing from the first column, or recycling selected components through the analytical column (**Figure 4E**). Finally, the comprehensive two-dimensional GC procedure is shown in **Figure 4F**. This method is

**Figure 3** (A) Single-column GC analysis result. (B) Selected incompletely resolved heartcuts from A are directed to a second column where improved separation is achieved. Here two heartcuts are performed. (C) Illustration of multidimensional analysis GC/MS, where the second dimension is a mass spectrum recorded at the mass spectral data acquisition rate. The success of this approach depends on the uniqueness of the mass spectrum at each point in the chromatogram. (D) The comprehensive two-dimensional GC method ideally spreads out the components in a two-dimensional space, according to the characteristics of each of the columns. Each component has a characteristic  $1^D$  and  $2^D$  retention time in the plane.

distinguished from the above by using a rapid modulation method to quickly alternate between focus and expel steps for solute eluting from  $1^D$ .

**Figure 5A** is a more detailed although still simplified diagram of the MDGC instrument. The heartcut valve is shown as V, although the different ways of performing the heartcut is not apparent. Thus, the Deans switch that relies upon pressure to shunt column 1 effluent to either the midpoint detector or to column 2 is one way to implement the heartcut. Other systems variously use valves or a combination of flow and shutting off stream flows to the monitor detector.

**Figure 4** Various arrangements for different coupled column techniques. (A) Multichromatography method – two columns are simply joined together. (B) Pressure-tuning. Supplementary flow ( $\Delta P$ ) at the mid-point alters the relative contribution of each column to the separation, so alters overall selectivity. (C) Normal MDGC. A switching valve for heartcut transfer, and monitor detector (det M) to show the  $^1D$  column result. (D) Multiple traps between  $^1D$  and  $^2D$  allow sequential heartcuts to be trapped and then separately eluted into the second column. (E) Recycle chromatography. The eluate from the first column can be recycled through the separation column a number of times to allow increased separation. (F) Comprehensive two-dimensional gas chromatography.

Typically, an MDGC method will focus on a limited number of heartcutting regions; however, more extensive analysis has been described where most of the sample is analyzed on both columns. The study of Gordon (24 heartcuts; **Figure 6**), each of 1–3 min duration of  $^1D$ , exemplifies this, where each heartcut had to be analyzed over a conventional timeframe, and gave a total analysis of about 2 days. In this case, the heartcuts were performed sequentially on separate sample injections, so each heartcut analysis involved one sample injection, one heartcut event, and one  $^2D$  analysis. The process was then repeated for each successive heartcut. Alternatively, it is possible to perform multiple heartcuts from  $^1D$  to  $^2D$ , with cryotrapping at the head of  $^2D$ . After these heartcuts are all co-collected for the single  $^1D$  analysis, the oven is cooled, the cryofluid turned off, and then all heartcuts are eluted as one run on the second dimension. Wilkins employed a series of heartcuts with parallel cryotrap, and at the conclusion of the first dimension separation,

**Figure 5** (A) Schematic description of a multidimensional gas chromatography arrangement, where a switching system or valve (V) is located between the two columns. The process of switching the flow between  $^1D$  and  $^2D$  or to the monitor detector (det M) is not shown. The auxiliary flow (aux) provides flow to the system to assist in the switching process, and/or to provide make-up flow into the column, which is not receiving flow from the  $^1D$  pre-column.  $^2D$  is normally a column of regular dimensions, and may incorporate a cryofocusing step at the head of the column. (B) The comprehensive two-dimensional gas chromatography arrangement essentially only requires a mechanism for modulation between the two columns, which provides a series of narrow peaks (at least four normally) to  $^2D$  for each  $^1D$  peak. The modulator (M) is shown near the column connection.  $^2D$  is normally a short, fast elution column.

each cryotrap was individually eluted into the second column. Suitable valve switching is required. Again, this involves multiple, full chromatographic development on  $^2D$ . In this case, parallel Fourier transform infrared (FTIR) and MS detection was used with the outlet flow of  $^2D$  unequally split to the detectors. Note that in all these cases,  $^2D$  is a conventional analysis in terms of column dimensions and conditions. Recently, a heartcutting/cryotrapping/fast-GC analysis was described, where the heartcut zone was cryofocused and then rapidly remobilized into a short, narrow bore capillary column for very fast GC discrimination of components. This allows the MDGC procedure to be completed within the same time as the first-dimension separation.

**Figure 6** Example of MDGC with multiple heartcuts (each heartcut required a separate injection) and separate  $^2D$  analysis of each heartcut.  $^2D$  result for heartcut event 14 is shown. ## Modes of MDGC

### Packed-to-Capillary

The situation of requiring analysis of a target compound that is severely overlapped by a major component is not isolated. If we analyze such a sample by using capillary GC then there is a risk that the major component will obscure the minor component, either because of the widening base of the major peak, or by the common observation of peak overloading that causes band asymmetry and broadening. Also, to increase the detectability of the small peak, it may be desirable to increase the sampled amount. This exacerbates the above problems. If a packed column is used in  $^1D$ , then more sample (both total, and target compound) can be introduced to the first column without too much overloading concern, and then heartcutting the target compound will lead to

most of the interfering compound being rejected from the  $^2D$  column. When the  $^2D$  separation is developed, the interferent will be much less likely to overload the capillary column than it normally would, and the target compound has an enhanced response because more of it enters  $^2D$ .

### Back-flushing

MDGC systems employ a switching valve at the confluence of the two columns. If the component(s) of interest are in the more volatile fraction of the injected sample then it is only necessary to pass this early eluting segment into  $^2D$ . Once this has been effected, the flows can be switched to cause the carrier gas to reverse-flow out the primary column, whilst the carrier still flows into  $^2D$  to allow the target compounds to be analyzed. Since the heavy compounds will not

have eluted far into the  $^1D$  column, they are relatively quickly eliminated from the inlet to  $^1D$ , and out the split vent. **Figure 4E** demonstrates this action. This allows faster turnaround of analysis, since it is never necessary to completely elute even the heaviest compounds completely through the analytical column.

### Multiple Heartcutting

A usual MDGC procedure may require multiple heartcuts. If these are transferred to  $^2D$  then each of the peaks in these zones will have an input peakwidth equal to the dispersion they have experienced on  $^1D$ . Also, peaks that swap positions on  $^2D$  compared with their  $^1D$  elution order may suffer worsened resolution on the two-column set, as they try to establish their reversed elution order as they travel along  $^2D$ . It is normally preferred that a cryofocusing event is used at the head of  $^2D$  to provide essentially a sharp band injection into  $^2D$ .

### Multiple $^2D$ Columns

The use of multiple (parallel) cryotrap or second dimension columns has been reported. The most common method in this category will employ two  $^2D$  columns, since this gives an improved performance without the added complexity of having more than two second-dimension columns. It is possible to divert the  $^1D$  effluent to either of the  $^2D$  columns.

### Multiple Parallel Traps

In the above instance, the discrete columns in  $^2D$  mean that effluent for  $^1D$  can be transferred to either of the columns, and a decision must be made as to which  $^2D$  column to use.

In conventional MDGC, it has been stated that a limited number of heartcuts can be performed. If the total sample must be subjected to the two-column analysis, then we face a dilemma: how can we study more of the effluent for  $^1D$ , but not run the risk of deteriorating the high performance of  $^2D$  by taking too large a heartcut into  $^2D$ . This can be solved in two ways. The first is to repeat the injection onto  $^1D$  and choose a different heartcut region for each injection. Eventually, it should be possible to analyze the whole sample on both dimensions – at the risk of significantly increasing the total analysis time.

The second is to heartcut successive or desired fractions into a range of parallel traps (**Figure 4D**) over the course of the development of the  $^1D$  separation, and then elute the contents of each of the traps into the  $^2D$  column as discrete events. Note that the above two methods involve discrete or sequential analysis of the selected heartcuts under essentially

standard conditions. Again, both approaches impose time penalties on the total analysis.

### Multiple Oven Operation

The use of multiple ovens (normally two) allows isolation of the optimum or desired conditions of analysis on  $^1D$  from the conditions used for analysis of the heartcut fraction on  $^2D$ . Once the heartcut has been delivered to  $^2D$ , it is then possible to independently complete the analysis on  $^1D$  without compromising the temperature conditions for analysis on  $^2D$ .

### MDGC with Selective Detection

Even though MDGC gives improved separation power, there is still an important requirement to achieve either solute identification through the use of MS, or using the specificity available with selective detection. Thus, two-column operation with a range of detection options is possible. Apart from the universally used flame ionization detector, the most popular detector for MDGC will be the mass spectrometer. Structural/identity information with full scan acquisition, and the selectivity and sensitivity available with selected ion monitoring makes the mass spectrometer a most attractive option. The use of other structural identification techniques such as FTIR has been reported by select groups. The complementarity of MS and FTIR is recognized when analyzing isomers of alkyl benzenes and alkanes. MS gives poor specificity toward the former, since they have similar MS fragmentation and the same molecular ion, whereas FTIR is able to distinguish positional isomer differences, due to different vibrational modes. However, for alkanes, FTIR is information-poor in its ability to distinguish homologs of an alkane class, whereas MS provides molecular ion information (and an indication of the chemical class) and so is able to correctly identify these species.

The use of simultaneous FTIR/MS using stream splitting to the parallel detectors was reported by Wilkins for petrochemical samples in an MDGC system. Asymmetric splitting was necessary because of the different sensitivities of the detection methods – most of the flow is diverted to the FTIR channel.

Any selective GC detector that provides the necessary molecular specificity for the analysis task may be used with MDGC methods.

### Comprehensive Two-Dimensional Gas Chromatography (GC $\times$ GC)

According to the previous definition, it is possible to increase the speed (frequency) of the heartcutting

operation to the point where each heartcut is of a similar duration as a single peakwidth, and to also operate these heartcuts contiguously. There is a valuable rationale for doing this, although taking the conventional wisdom of MDGC, it would not be logical to do MDGC in this manner. Conventionally, only selected target zones would be chosen for enhanced separation – this fast, continuous heartcutting process used in  $GC \times GC$  appears to be nondiscriminative and so is difficult to rationalize. Second, if  $^2D$  is to provide analysis of these heartcuts effectively, it is impossible to use the methods or approaches described above – discrete trapping events for each heartcut, or parallel traps, and so forth. If the procedure involves direct transfer from a single  $^1D$  to a single  $^2D$  column, then  $^2D$  will have to be capable of analyzing each heartcut within the time duration of the heartcut. This will then allow  $^2D$  to complete the analysis of each heartcut before the next heartcut is delivered to it. This essentially describes the comprehensive ( $GC \times GC$ ) technique. The multiplicative operation ( $\times$ ) is deliberately intended to indicate that the separation power of  $^1D$  is combined with the separation power of  $^2D$  over the total sample, through multiplying their individual peak capacities. Figure 1C is a diagram that puts this process into context. Giddings considered this expansion in separation space some time ago, but did not indicate how it could be achieved. The only effective way to do this is to ensure that each  $^1D$  peak is sampled a multiple of times (at least three to four times) into  $^2D$ . Clearly this technique demands a novel approach to implementing the coupling of the columns, and this is done through use of a ‘modulator’. Figure 5B is a schematic diagram of the  $GC \times GC$  instrument, with the modulator located near the junction of the two columns. Both mass-conservative and peak subsampling modulators have been described. Figure 7 includes seven different types of modulators for  $GC \times GC$ . Those that use either elevated or reduced temperature (1–5) are denoted  $\Delta T$ , and some cryogenic types also have supplemental heating to aid expelling of the trapped bands to  $^2D$ . For the mass-conservative modulator, the first and second dimension columns may be directly joined, without requiring valves between the columns. The process therefore requires that the part or segment of the peak entering the modulation region should be compressed in space along the column into a concentrated packet, and then rapidly introduced into dimension 2. The initial way this was done was by application of heating to accelerate the chromatographic band in an accumulation region (often a thicker film stationary phase column). Today, most modulators of the mass conservative type

**Figure 7** Schematic representations of various modulator types used in comprehensive two-dimensional gas chromatography. (1 and 2) Use alternating high temperature at a thick segment of column to collect then expel solute from  $^1D$  into  $^2D$ . (3–5) Rely on cold-trapping and then rapid heating of the column segment for the collect/expel process. The heating may be provided by a secondary heated gas flow, or just the stirred oven. (6 and 7) Are valve-based sampling methods which subsample the peak from  $^1D$  into  $^2D$ .

employ cryogenic cooling. This cryofocuses the selected part (or all) of the peak into a very narrow band, and when the cooling is removed from that column segment, the capillary column heats up and allows the trapped band to pass rapidly to  $^2D$  to permit its fast analysis (and separation of co-trapped compounds). This necessitates repetitive sampling or modulation across the total chromatogram, which generates a series of contiguous second-dimension chromatograms. To adequately display these  $GC \times GC$  data, a two-dimensional plot of the data is prepared, with the two axes being the total analysis time (or first-dimension elution time) and the second-dimension time (or modulation period, e.g., 4 s). This might be implicit in the nature of the separation space shown in Figure 1C and Figure 3D is a more realistic illustration of the  $GC \times GC$  result. Peaks are now spots in a two-dimensional plan, much like those spots found in thin-layer chromatography. The power of the technique resides in (1) its very high peak capacity which permits a much greater separation of components, (2) the increase in peak

### Introduction

High-temperature gas chromatography (HTGC) is an extension of conventional gas chromatography (GC) to higher working temperatures. It is generally accepted to use the term 'high temperature' for GC operations starting at the working limit of conventional GC ( $\sim 350^{\circ}\text{C}$ ). The limit for HTGC is not clearly defined but is  $\sim 450^{\circ}\text{C}$ . At a first glance, this extension of the working temperature appears only marginal, yet in practice it is significant. By increasing the maximum working temperature, the application range, in terms of mass units of compounds that can be analyzed, can be extended from  $\sim 600$  to above 1000 Da, depending on the nature and volatility of the compounds. This opens the opportunity to use HTGC for applications that are handled, by general consensus, by alternative chromatographic methods, such as the omnipresent high-pressure liquid chromatography (HPLC).

However, particularly in cases of complex mixtures of more or less apolar compounds, which can be only poorly resolved by HPLC, HTGC is the method of choice for both quantitative and qualitative analysis, because both the separation efficiency and the signal-to-noise ratio of HTGC are significantly higher compared to alternative chromatographic techniques.

Gas chromatographic systems designed for conventional GC cannot be used easily for HTGC work. In practice, HTGC needs special instrumentation. The injector, column oven, detectors, carrier gas,

and, last but not least, the capillary columns should be appropriate for high-temperature operation.

### Instrumental Considerations

#### Injection Techniques

For sample introduction in HTGC, split, splitless, on-column injection, or combinations of the latter, the programmable temperature vaporizing (PTV) injector are suitable. However, with the exception of cold on-column injection, none of these introduction systems fulfill the requirements of an adequate HTGC injection device and guarantees reliable results.

All heated injector systems are well-known sources of error, due to the possibility of artifact formation, and in many cases, split, splitless, or PTV injection provides discrimination of high-boiling compounds by thermal degradation. Only cold on-column injection ensures quantitative sample transfer from the injection port into the capillary column without thermal stress of the samples or discrimination of high-boiling compounds.

In addition, by cold on-column injection of crude samples into a deactivated, but uncoated, precolumn (retention gap), installed in a separate GC oven, the analytical column can be protected from nonvolatile by-products, and the injected sample volume can be significantly enlarged. The large retention gap and the analytical column are linked by a heated transfer line (GC–GC). The retention gap is heated separately and programmed from  $\sim 70^{\circ}\text{C}$  to a temperature  $50^{\circ}\text{C}$  below the maximum working temperature of the analytical column. The temperature program of the analytical column is not started until the temperature of the retention gap exceeds  $120^{\circ}\text{C}$ . A representative example for the direct injection of a

### Introduction

High-temperature gas chromatography (HTGC) is an extension of conventional gas chromatography (GC) to higher working temperatures. It is generally accepted to use the term 'high temperature' for GC operations starting at the working limit of conventional GC ( $\sim 350^{\circ}\text{C}$ ). The limit for HTGC is not clearly defined but is  $\sim 450^{\circ}\text{C}$ . At a first glance, this extension of the working temperature appears only marginal, yet in practice it is significant. By increasing the maximum working temperature, the application range, in terms of mass units of compounds that can be analyzed, can be extended from  $\sim 600$  to above  $1000\text{ Da}$ , depending on the nature and volatility of the compounds. This opens the opportunity to use HTGC for applications that are handled, by general consensus, by alternative chromatographic methods, such as the omnipresent high-pressure liquid chromatography (HPLC).

However, particularly in cases of complex mixtures of more or less apolar compounds, which can be only poorly resolved by HPLC, HTGC is the method of choice for both quantitative and qualitative analysis, because both the separation efficiency and the signal-to-noise ratio of HTGC are significantly higher compared to alternative chromatographic techniques.

Gas chromatographic systems designed for conventional GC cannot be used easily for HTGC work. In practice, HTGC needs special instrumentation. The injector, column oven, detectors, carrier gas,

and, last but not least, the capillary columns should be appropriate for high-temperature operation.

### Instrumental Considerations

#### Injection Techniques

For sample introduction in HTGC, split, splitless, on-column injection, or combinations of the latter, the programmable temperature vaporizing (PTV) injector are suitable. However, with the exception of cold on-column injection, none of these introduction systems fulfill the requirements of an adequate HTGC injection device and guarantees reliable results.

All heated injector systems are well-known sources of error, due to the possibility of artifact formation, and in many cases, split, splitless, or PTV injection provides discrimination of high-boiling compounds by thermal degradation. Only cold on-column injection ensures quantitative sample transfer from the injection port into the capillary column without thermal stress of the samples or discrimination of high-boiling compounds.

In addition, by cold on-column injection of crude samples into a deactivated, but uncoated, precolumn (retention gap), installed in a separate GC oven, the analytical column can be protected from nonvolatile by-products, and the injected sample volume can be significantly enlarged. The large retention gap and the analytical column are linked by a heated transfer line (GC–GC). The retention gap is heated separately and programmed from  $\sim 70^{\circ}\text{C}$  to a temperature  $50^{\circ}\text{C}$  below the maximum working temperature of the analytical column. The temperature program of the analytical column is not started until the temperature of the retention gap exceeds  $120^{\circ}\text{C}$ . A representative example for the direct injection of a

**Figure 1** FID chromatogram of the direct injection of the neutral fraction of Polish Tall oil.

crude extract via a large, separately heated retention gap is shown in **Figure 1**.

### Carrier Gas, Carrier Gas Control

In GC, the most common carrier gas is helium, followed to an increasing degree by hydrogen. When expressed in plate numbers, the separation efficiency of a column neither seems to be significantly influenced by the nature of the carrier gas, nor by the column temperature, and, at a first glance, both gases are equally well suited. Looking at it more closely, it becomes obvious that the separation power of a capillary column strongly depends on both parameters. When the efficiency of a column is measured by *TZ* values (*TZ* = Trennzahl, separation number), it becomes clear that the separation efficiency decreases at higher temperatures. In other words, the higher the retention temperature at which a given compound elutes, the lower the resolution. In order to decrease the retention temperatures and to extend the application range of HTGC, carrier gas flow control or flow programming instead of pressure control is recommended. This in turn will lead to nonoptimal flow conditions, which has negative impact on separation efficiency. With helium as carrier gas this effect is

significant; with lower-viscosity hydrogen this effect is negligible.

Therefore, most of the proprietary HTGC applications are carried out with hydrogen as a carrier gas.

### Detectors

The detectors used in HTGC are, apart from the highly versatile flame ionization detector (FID), the phosphorus/nitrogen-selective alkali-flame ionization detector (AFID), the atomic emission detector, the inductively coupled plasma (ICP)-mass spectrometer, and, last but not least, mass spectrometers with electron impact and chemical ionization ion sources (EI/CI-MS).

The FID and the AFID have to be equipped with high-temperature resistant flame tips, temperature-protected electronic devices, and reinforced detector heating with detector blocks from bronze or stainless steel. In order to avoid 'cold spots' at the very end of the separation column, it is important that heat transfer is efficient.

The AFID is identical to the FID, except that an alkali metal salt source is placed between the burner tip and the collector. The response of the AFID strongly depends on the concentration of hydrogen in

**Figure 2** Diagram of a high-temperature glass capillary interface linked to quadrupole mass spectrometer. The enlarged presentation shows the entrance into the ion chamber with an additional electrical heater and CI reagent gas entrance coaxial to the interface capillary. (Reproduced from Blum W, Ramstein P, and Eglinton G (1998) Simultaneous coupling of supercritical fluid chromatography and high temperature glass capillary gas chromatography to a mass spectrometer. *Journal of High Resolution Chromatography and Chromatography Communications* 11: 441–448.)

the gaseous boundary of the alkali metal bead. Accurate control of the hydrogen flow, and, if hydrogen is used as mobile phase, of the carrier gas, is required and constant carrier gas flow regulation is mandatory.

Apart from the FID, the mass spectrometer is the most widely used detection device in capillary GC. However, most of the commercially available GC–mass spectrometry (MS) systems do not fulfill the criteria for use with HTGC. The most serious problems encountered are the coupling of the HT-capillary column to the ion source, the choice of carrier gas, and, if CI is used, the reagent gas, and the limited scan range of most GC–MS instruments.

An HTGC–MS system should have a scan range up to  $\geq 1500$  Da. It should be equipped with turbo molecular pumps resistant to corrosive gases, with sufficient pumping capacity to deal with a continuous flow of gas mixtures such as ammonia (CI reagent gas) and hydrogen (carrier gas). The interface temperature should be kept at  $\sim 400^\circ\text{C}$  and as constant as possible along the transfer line up to the very end, in order to avoid ‘cold spots’ and to run the ion source at significantly lower temperatures as the column or the interface line.

Simply inserting the exit of a flexible fused-silica capillary directly into the ionizing chamber, and setting the ion source temperature to the maximum, as is common practice, can create serious background from degradation products of the polyamide outer

coating, and will deteriorate the quality of the mass spectra, in particular of the CI spectra. If aggressive reagent gases, such as ammonia, are introduced in CI mode, the background can rise to intolerable levels. A highly inert, coaxial HTGC–MS glass interface system can be used in both electron impact (EI) and CI modes at moderate ion source temperatures, which takes all requirements mentioned above into account (see Figure 2).

### High-Temperature Capillary Columns

The heart and the soul of any GC system is the separation column. Historically, three support materials were used in capillary GC. In chronological order of column development this was metal, borosilicate glass, and fused silica.

Modern GC is based almost exclusively on fused-silica capillaries, which has consequences for HTGC. Despite the fact that the thermal stability of the common polyamide clad columns could be improved to allow temperatures up to  $400^\circ\text{C}$ , one inherent problem of fused-silica remains. It was reported that already at ambient temperatures, low molecular gases like helium or hydrogen permeate through the fused-silica capillary wall and its outer coating. This will inevitably limit the application range for fused silica, in particular for HTGC applications under pressure regulation.

Although a systematic comparison among the various high-temperature resistant supports has never been undertaken, for most of the few groups dealing with fundamental applications in HTGC, borosilicate glass is still the favorite support material.

Nearly all stationary phases used in HTGC are polysiloxanes, which, apart from a few exceptions, bear reactive termini such as OH or CH<sub>3</sub>O groups. Compared to coatings based on traditional end-capped polysiloxanes, OH or CH<sub>3</sub>O terminated polymers showed a significantly improved thermal stability when coated on silanol-rich surfaces. Pronounced covalent bonding of the coatings leads to increased inertness and less catalytic degradation.

The key mechanism of the thermal degradation of OH-terminated polysiloxane coatings in an inert environment is given in **Scheme 1**. Polysiloxane chains with terminal silanol groups can undergo nucleophilic substitution, which leads to the formation of low molecular weight cyclic silyloxy compounds (bleeding). The thermal depolymerization is governed mainly by structural and kinetic factors.

Any measure that avoids or suppresses this 'unzipping' mechanism results in improved thermal stability of the coating.

The degree of thermal degradation can be decreased by lowering the density of the silanol group. This can be achieved by further polymerization of the stationary phase by addition of so-called polyfunctional cross-linkers, e.g., trimethoxysilane, as shown in **Scheme 2**.

Moreover, the covalent chemical bonding between the mobile phase and the column wall stabilizes the coating. The cross-linking takes place even at room temperature by partial condensation of terminal methoxy groups with surface silanol groups, or vice versa. At elevated temperatures, i.e., during thermal conditioning of the column, it proceeds by intramolecular nucleophilic substitution and release of volatile polymer substituents like benzene. The stabilization of the coating at elevated temperatures by autocross-linking is characteristic for OH-terminated polysiloxane phases. In conventional GC, comparable reactions are of minor importance.

The thermal stability of polysiloxane stationary phases is also influenced by structural factors. Chemical modifications of the polymer backbone, e.g., by introducing planar groups such as phenyl, diphenyl, diphenylether, etc., reduce the flexibility of the polysiloxane backbone and its ability to undergo the 'unzipping' reaction shown in **Scheme 1**. Consequently, the maximum working temperatures of the respective polymer increases (see **Tables 3–5**). The most common polymer modifications are shown in **Scheme 3**.

Besides the modifications of the silicone backbone, the order of the substituents along the polymer chain is of fundamental importance for thermal stability. If a polymer bears different polar or polarizable functional groups, as is common for most of the medium-polarity phases, the thermal stability of the coating will be improved if the polymer

phases are not designed for HTGC, and can be used up to 350–370°C only.

The stationary phases listed in **Tables 3–5** are specially designed for high-temperature work. These phases can easily be synthesized on a laboratory scale. The underlying methods are reported and are easy to reproduce.

## Applications

### Organic Geochemistry

In organic geochemistry HTGC is an established tool. The applications are mainly focused on aspects

such as simulated distillation of crude oils and petroleum residues, and the analysis of high molecular weight waxes and biomarkers and in geochemical petroleum prospecting (**Figure 3**).

### Simulated Distillation

Distillation is a standard procedure to classify crude oils into a manageable number of compounds. HTGC techniques were successfully introduced to reduce the analysis time significantly. Since the first report on simulated distillation of heavy petroleum fractions by HTGC up to a true boiling point of 800°C, the usefulness of simulated distillation, in

**Figure 3** FID chromatogram of a homologous series of aliphatic hydrocarbons C<sub>30</sub>–C<sub>60</sub> separated on a SOP-50-PFD (unpublished results).

order to classify fossil materials with a wide carbon number distribution, is generally accepted in the petrol industry. Usually simulated distillation is performed on short 5–10 m, thin film, apolar coated capillary columns.

### Waxes and Biomarkers

The higher molecular weight hydrocarbons (>C<sub>40</sub>) and asphaltenes are important constituents of crude oils. Despite their relatively low concentration, they can cause serious problems related to crystallization and disposition of paraffin waxes during oil production and transportation, and in formation of tar mats. Thus, it is important to have a method, such as HTGC or HTGC–MS, for accurate assessment of the weight of wax fractions in crude oil, as well as an accurate assessment of the associated asphaltene fraction.

Biomarkers are compounds whose carbon skeletons can be unambiguously linked with known natural precursors. They have been used to obtain information about the source, disposition, biodegradation, migration, and other information concerning the biochemistry of crude oils. Possible sources of higher molecular weight hydrocarbons include waxes and wax esters from precursors in living organism such as higher-plant cuticular waxes, or aliphatic material from algaenans, which can provide an important source of *n*-alkanes in marine oils, etc.

The investigation of other classes of biomarkers such as chlorines and porphyrins has shown a similar trend toward the discovery of novel high molecular mass compounds. One reason for the rapid increase in the number of identified biomarkers is the availability of HTGC–MS (Figure 4).

### Natural Products

Many studies have shown that HTGC, in particular in combination with MS, can extend the application range for the rapid analysis of complex natural product samples. Although complete structure elucidation of the separated compounds solely by MS has, in most cases, a poor prognosis, modern high-resolution MS/MS techniques in combination with HTGC permit fast characterization of several classes of natural products such as *n*-alkanes and alkenes, steroids, terpenes, alcohols, aldehydes, carboxylic acids, esters, triglycerides, amino acids, vitamins, and oligosaccharides.

### Plant Materials, Lipids

The separation and identification of the volatile ingredients of plant extracts is a demanding task. Most of the extracts cover a wide boiling range, in which the high-boiling compounds remain unidentified. Representative applications are the identification of long-chain triterpenoidylesters in smoke from biomass combustion and the characterization of

**Figure 4** HTGC-MS EI-total ion current chromatogram (TIC) of a Julia creek oil shale extract. Column: OV-61-OH, 10 m  $\times$  0.2 mm, glass. Carrier gas: H<sub>2</sub>. (Reproduced from Blum W, Ramstein P, and Eglinton G (1988) Simultaneous coupling of supercritical fluid chromatography and high temperature glass capillary gas chromatography to a mass spectrometer. *Journal of High Resolution Chromatography and Chromatography Communications* 11: 441–448.)

triacylglycerols containing oxygenated fatty acid acyl groups (Figure 5).

### Triglycerides and Wax Esters

Triglycerides, fatty acids, and fatty acid-esters are the main ingredients of vegetable oils and animal fats. The separation and characterization of the complex mixtures of saturated and unsaturated, long-chain fatty acids, mono-, di-, and triglyceride, and fatty acid esters is of interest in food industry in order to classify and differentiate the various crude fats and oils. HTGC and HTGC-MS are particularly powerful tools for the separation and characterization of complex mixtures of high-boiling, long-chain fatty acid esters (wax esters).

As mentioned before, in GC low retention temperatures are generally advantageous, because the higher the chosen working temperature, the lower is the separation efficiency. Therefore, in practice of HTGC not only the maximum working temperature of a column is of importance, but also the retention power of its coating. In this context it was reported that the system-inherent low retention power of perfluoroalkyl-polysiloxane coatings significantly reduces the retention temperatures, compared to nonfluoroalkyl-substituted polysiloxanes, without any loss of column efficiency.

The extension of the working range of HTGC on a poly(diphenyl-perfluorodecylmethyl) siloxane phase (SOP-50-PFD, see Table 5) is demonstrated in HTGC and HTGC-MS/MS investigations of crude comb-waxes of various honey bee species. By pattern recognition of the resulting wax-ester chromatograms, a chemotaxonomic distinction among the honeybee species was feasible (Figure 6).

### Oligosaccharides

Free or covalently bound oligosaccharides (glycoproteins, glycolipids) are widely distributed in nature. For example, it has been suggested that most common proteins are glycosylated and that glycosylation plays an important role in biological function, dynamics, and physiochemical properties. ‘Sugar mapping’, e.g., by HTGC-MS/MS has proven to be a useful tool in order to characterize the complex oligosaccharide mixtures released from glycoproteins. Representative for this application is the analysis of the complex mixture of O-linked oligosaccharides after premethylation, released from muscin glycopeptides from porcine small intestine, as shown in Figure 7.

### Industrial Products

Most of the reports dealing with HTGC analysis of industrial products made on a ton scale are

**Figure 5** Representative HTGC–MS total ion current trace of the ester fraction in smoke extract from Castanha-do-Para. Column: OV-1701-OH, 20 m × 0.3 mm, glass. Carrier gas: He. investigations of synthetic organic chemicals after release into the aquatic environment. Many of them are toxic at low concentrations and accumulate in sediments or organisms. In most of the cases pre-concentration of the sample involves liquid–liquid extraction, e.g., with dichloromethane, or solid-phase extraction.

The compound classes that can be tackled successfully by HTGC cover a wide range of organic chemicals such as polychlorinated biphenyls, antioxidants, and ultraviolet (UV) stabilizers, non-ionic surfactants, commonly used as wetting agents or emulsifiers, polymer degradation products of bisphenol-A epoxy resins, rolling mill oils, etc. Representative for the HTGC analysis of industrial products is the separation of an artificial mixture of omnipresent antioxidants and UV stabilizers, up to molecular weights above 1000 Da (Figure 8).

## Concluding Remarks

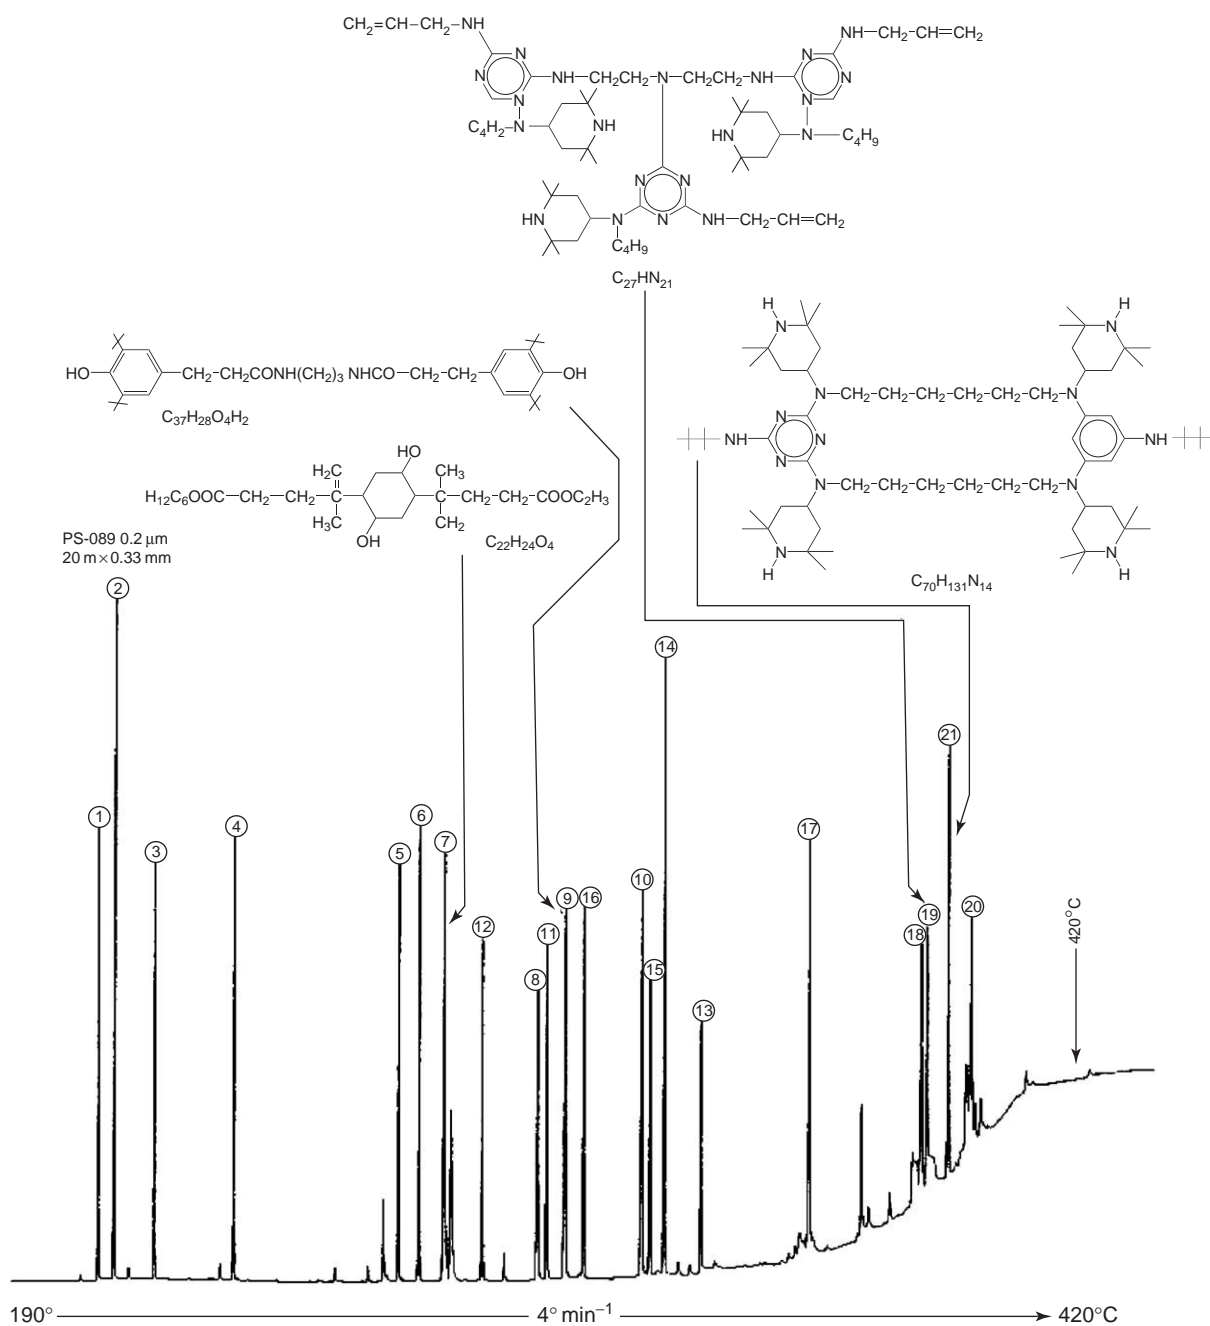

Gas chromatography, in particular HTGC, is a mature analytical technique. The underlying HTGC column technology was developed more than 15 years ago. Since then only little innovation was added. What has changed over the years is the attitude of the succeeding generation of chromatographers, from column makers to column consumers. Today, column preparation is fully commercialized. The secret behind outstanding HTGC applications, the deeper knowledge of the ‘art and the science’ of column technology, and the craft of column preparation is no longer a subject of education of analytical chemists, and faded, more or less, into oblivion. Many of the outstanding applications, published in the late 1980s and the early 1990s, can hardly be reproduced on the basis of today’s commercially available columns.

**Figure 8** FID chromatogram of antioxidants and UV stabilizers. Column: PS-089, 20 m  $\times$  0.3 mm, glass. Carrier gas:  $\text{H}_2$ . (Reproduced from Blum W and Damasceno L (1987) High temperature glass capillary gas chromatography using OH-terminated polysiloxane stationary phases. Separation of antioxidants and UV stabilizers. *Journal of High Resolution Chromatography and Chromatography Communications* 10: 472–476.)

The most important detector in capillary column chromatography is the mass spectrometer. Experience has shown that any chromatographic method that cannot be coupled with a mass spectrometer remains of little practical relevance in the long term. In this context, it must be taken into consideration that high-temperature GC–MS was developed during a transitional phase, at a time when HPLC–MS was

still in its infancy and of limited practical importance. This has changed over the years. The sensitivity and simplicity of modern HPLC–MS systems, equipped with electrospray ionization sources (ESI), can easily compete with GC–MS instruments. Therefore, nowadays most of the separation problems in the medium and high molecular mass range are tackled by HPLC–MS.

Although in some reports the future of HTGC and HTGC–MS is pointed out as promising, some doubts remain. HTGC was and is a demanding borderline technique, requiring experienced specialists to successfully put into action. The necessary equipment is only partially commercially available and has to be modified and adapted to specific tasks. Most of the outstanding applications are performed in a handful of key laboratories, active in this field for many years, where the art of HTGC column making is not completely forgotten. In their hands the method is a mass powerful tool and may have a future. Many complex apolar and medium molecular mass or artificial mixtures, such as lipids and waxes, wax esters, polysaccharides, additives, fashionably analyzed nowadays by HPLC or HPLC–MS, could be tackled much more successfully by HTGC and HTGC–MS, due to the significantly higher separation efficiency of GC. In these application fields HTGC is difficult to beat, and there the method may find a niche.

## High-Speed Techniques

**P J Marriott and R A Shellie**, RMIT University, Melbourne, VIC, Australia

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

There are many definitions of fast gas chromatography (GC). For some, the definition of fast may be ‘that we achieved the result in less time than we did yesterday’. Others adhere strictly to rules such as ‘the inherent speed of a given separation is best defined by the width of peaks’ and then seek to minimize this width for all peaks. In practical GC, the best definition of fast will be dependent on the analysis task at hand. The approach that an analyst accepts as a ‘fast’

method will be determined by the sample, and also by the type (or amount) of information required from the sample. Typical approaches can be exemplified by various ways and information can be derived from GC as follows:

- For the analysis of complex samples, for example, detailed hydrocarbon analysis of naphtha and gasoline, or flavor and fragrance analysis, often the only suitable approach to speeding up the analysis is to implement a method that provides a short analysis time but still achieves a very high peak capacity.
- Where the sample is less complicated, or where only a small number of components in the sample are of interest, the requirement for very high peak capacity may be relaxed. Here, the main criterion for selecting the appropriate conditions is to ensure

that only the target analytes are separated, and only with the minimum resolution required to provide a sufficiently accurate result.

- Maximizing the selectivity of the chromatographic system may allow a reduction of analysis time. This type of approach is especially useful for providing improved resolution for samples of low to moderate complexity.
- A further powerful approach is to use a selective detector. This can simplify method optimization for specialized analyses because the selectivity of the detector toward the target analyte may reduce the requirement for chromatographic resolution of the target analyte from interferences.

For many applications only the peakwidth definition will be appropriate; however, the 'less time than yesterday' definition will also be satisfactory for many analyses. For the purpose of clarity, in this article the authors have chosen to use the following terms:

1. High-speed analysis: this description shall describe GC analyses that have short analysis times, but do not necessarily satisfy the requirements of the peakwidth description. These analyses will generally be achieved by sacrificing resolution, by increasing selectivity toward a target analyte, by using selective detection, or a combination of any of these.
2. Fast gas chromatography: this term will be used here to describe analyses that maintain high efficiency. Fast-GC, very fast GC, and ultrafast-GC – GC can be distinguished by the relative widths of peaks in the chromatogram. A list of typical characteristic peakwidths defining each category of GC is given in Table 1.

Regardless from which approach the most appropriate conditions for the required analysis are drawn, it is important to consider some fundamental GC theory.

**Table 1** Comparison of calculated plate number, retention time, and peak-width at half-height using standard, fast, very fast, and ultrafast GC

Type of analysis	$d_c$ ( $\mu\text{m}$ )	$L$ (m)	$N$	$t_R$ (s)	$\omega_n$ (s)
Standard	320	25	90 000	160	1
Fast	50	10	260 000	60	0.2
Very fast	50	1	25 000	2.0	0.03
Ultrafast	50	0.3	7 000	0.40	0.01

Conditions for these calculations are:  $\beta = 62.5$ , compound = hexane,  $T = 330$  K, helium carrier gas. See the above reference for details of the calculation program.

## Some Fundamental GC Theory and Routes toward High-Speed Analysis

In practical GC, it is important that the number of theoretical plates required ( $N_{\text{req}}$ ) in order to provide a desired resolution ( $R_s$ ) for a given pair of components (defined by  $\alpha$  and  $k$ ) can be calculated. This can be achieved by using the Purnell equation (eqn [1]):

$$N_{\text{req}} = 16R_s^2 \left( \frac{\alpha}{\alpha - 1} \right)^2 \left( \frac{k + 1}{k} \right)^2 \quad [1]$$

where the separation factor  $\alpha = t'_{R2}/t'_{R1}$ , and retention factor  $k$  refers to the last eluting peak in the pair.  $R_s$  is measured experimentally as

$$R_s = \frac{\Delta t_R}{4\sigma} \quad [2]$$

Equation [1] can be applied to assist in the selection of the appropriate chromatographic conditions to provide the minimum resolution required for the analysis task. Baseline resolution is achieved at  $R_s > 1.5$ , and will be sufficient to provide accurate quantitative data in most applications. In many cases solutes tend to be over-separated ( $R_s \gg 2$ ), and excess resolution equates to excessive analysis time.

By extending this theory it is possible to determine the minimum time in which sufficient resolution of a critical pair of peaks can be achieved (eqn [3]):

$$t_R = 16R^2 \left[ \frac{H}{\bar{u}} \right] \left[ \left( \frac{(1+k)^3}{k^2} \right) \left( \frac{\alpha}{\alpha - 1} \right)^2 \right] \quad [3]$$

Equation [3] reveals that the column temperature (because this influences  $k$ ), carrier gas linear velocity (which will change the plate duration (the Purnell criterion)  $H/\bar{u}$ ), and column selectivity (affects  $k$ ;  $\alpha/\alpha - 1$ ) are important considerations for reducing analysis time.

Since it is likely that the critical pair of components will not be the last eluting peaks, they do not provide the best indication of the total analysis time; however, this can be given by eqn [4]:

$$t_R = (L/\bar{u})(k_n + 1) \quad [4]$$

where  $L$  is the column length,  $\bar{u}$  the average linear velocity of the carrier gas, and  $k_n$  the retention factor of the last eluting compound in the sample.

Equation [4] is very useful for deducing the general operating requirements of high-speed analysis. The use of a short column, a higher than usual carrier gas velocity, and relatively small retention factors (which can be easily achieved by using high temperature and/or thin film columns), can reduce analysis times

**Figure 1** The use of a selective stationary phase column for the high-speed analysis of ethanol in unleaded petrol.

significantly. There will, however, be a penalty associated with reducing the analysis time by using these straightforward steps, namely a reduction in the resolving power due to reduced peak capacity and increased band broadening. Equation [4] does not implicitly allow the effective resolution of the system to be evaluated.

Column selection and stationary phase selectivity can play a major role in reducing the requirement for very high plate numbers. For example, a relatively new PLOT capillary column, which uses a polar adsorbent as the stationary phase, has unique selectivity toward oxygenated compounds. The capability of such a stationary phase column to provide excellent separation of oxygenates in the presence of hydrocarbons is illustrated in **Figure 1**. Stationary phase selectivity can be manipulated to achieve better separation of target compounds in a shorter time than would normally be required using a nonselective column, but stationary phase optimization will be limited to the analysis of low-complexity samples, i.e., those containing fewer than say 50 components, or to mixtures containing a small number of target analytes. This is supported by statistical overlap theory, in which the extent of peak overlap in gas chromatograms of complex mixtures can be predicted.

Other specialized high-speed GC alternatives include the use of multicapillary columns, packed columns, and flash-GC. Multicapillary columns are made by combining some 900 capillaries, each with a  $d_c$  of 40  $\mu\text{m}$  into a bundle of about 1 m length. These multicapillary columns allow the use of high flow rates and are characterized by a high sample capacity. The 1980s saw some promising work in the area of fast-GC using micropacked columns; for example, the separation of a mixture of alkanes was performed using a short 320  $\mu\text{m}$  i.d. column, packed with 10  $\mu\text{m}$  particles. Flash-GC devices are based

upon resistively heated metal capillary columns, allowing extremely high heating rates and very fast cooling times. These latter approaches cannot be considered mainstream technologies, and no further comment shall be made in the present article.

## Routes toward Fast Gas Chromatography

The basic Golay equation (eqn [5]) describes height equivalent to one theoretical plate ( $H$ ) in terms of the average linear carrier gas velocity for a capillary column:

$$H = \frac{B}{\bar{u}} + C_G \bar{u} + C_L \bar{u} \quad [5]$$

where  $B$  represents the longitudinal gaseous diffusion;  $C_G$  and  $C_L$  are the resistance to mass transfer in the gas phase and liquid phase, respectively. The hyperbolic van Deemter plot is obtained by plotting  $H$  against  $\bar{u}$  from eqn [5]. This hyperbola has a minimum at

$$H_{\min} = 2\sqrt{B(C_G + C_L)} \quad [6]$$

The Golay equation can be expanded (see eqn [7]) to outline some fundamental relationships that allow the analyst to set guidelines for developing a high-resolution fast-GC approach; some of these are discussed below:

$$H = \frac{2D_G}{u} + \frac{(1 + 6k + 11k^2)r^2}{24(1 + k)^2 D_G} u + \frac{2kd_f^2}{3(1 + k)^2 D_L} u \quad [7]$$

## New Method Development

**Column dimensions** Smaller-diameter columns often provide a direct route to speeding up analyses. In fact, the separation of 15 peaks in  $\sim 2$  s using a 1.2 m  $\times$  34.5  $\mu\text{m}$  capillary column was demonstrated as early as 1962 (see **Figure 2**). By reducing the column diameter  $d_c$ , a higher efficiency per unit length ( $L$ ) is achieved. This can be demonstrated by examination of eqn [7], where it is clear that two different situations can occur. For large  $\beta$  (phase ratio) values the  $C_L$  term can be neglected, for small  $\beta$  values the  $C_L$  term determines efficiency.

Where resistance to mass transfer in the gas phase controls  $H$ , the  $C_L$  term may be ignored; thus,

$$H_{\min} = 2(BC_G)^{1/2} = r\sqrt{\frac{1 + 6k + 11k^2}{3(1 + k)^2}} \quad [8]$$

For high  $k$  values it has been shown experimentally that  $H_{\min}$  approaches  $d_c$ . The minimum  $L$  required to

produce 100 000 theoretical plates has been calculated for the most common commercially available capillary column dimensions. These respective column lengths are reported in Table 2, where it is apparent that equivalent plate numbers are achieved using significantly shorter smaller-diameter columns. Also, as  $d_c$  is reduced, the optimal average linear carrier gas velocity  $\bar{u}$  is also higher. Both of these factors lead to faster GC analysis (see eqn [4]).

Whilst the advantages of smaller-diameter columns are apparent, typically there has been limited implementation of these columns for fast-GC. This can be attributed to a number of factors, such as the need for high column head pressure, which were historically seen as distinct limitations; however, most of these can be overcome by the use of modern instrumentation. Narrow bore capillary columns also have a low sample loading capacity, so small injection sizes (of the order of a few nanograms) are required.

Smaller-diameter columns generally contain thin film stationary phase coatings, and will require care in manufacture to reduce column activity. Recent advancements in capillary column technology have allowed more routine application of smaller-diameter

<sup>a</sup>These calculations are true for columns with large  $\beta$  values.

<sup>b</sup>50  $\mu\text{m}$  i.d. capillary columns are not commonly available at present.

**Figure 3** Fast-GC analysis of lime essential oil using a  $5\text{ m} \times 50\text{ }\mu\text{m}$  capillary column with  $0.05\text{ }\mu\text{m}$   $d_f$  with hydrogen as the carrier gas. One microliter of a 1% essential oil in *n*-hexane solution was injected using a split ratio of 750:1. The column head pressure was 880 kPa and the GC oven was temperature programmed from 50 to  $150^\circ\text{C}$  at  $80^\circ\text{C min}^{-1}$ , to  $200^\circ\text{C}$  at  $70^\circ\text{C min}^{-1}$ , and finally to  $250^\circ\text{C}$  at  $55^\circ\text{C min}^{-1}$ .

columns. Columns of 100  $\mu\text{m}$  i.d. with various stationary phase coatings are common in all column manufacturer catalogs. With ever-improving instrument capabilities, it is expected that demand for even smaller-diameter columns will rise. The potential of ultra-narrow bore columns for high-resolution fast-GC analysis is illustrated in Figure 3 by the analysis of lime essential oil.

**Carrier gas selection and carrier gas velocity** The correct choice of carrier gas has a dramatic effect on analysis speed. For columns with large  $\beta$ ,  $h_{\text{min}}$  is essentially the same for nitrogen, helium, and hydrogen. However, hydrogen is the best choice because its  $u_{\text{opt}}$  is higher than that of the other gases. Optimum carrier gas velocity is proportional to the diffusivity in the gas phase, and since  $D_G$  is approximately inversely proportional to the square root of the molecular weight of the carrier gas,  $u_{\text{opt}}(\text{H}_2) = 1.4 \times u_{\text{opt}}(\text{He})$ , and  $= 3.7 \times u_{\text{opt}}(\text{N}_2)$ . The use of hydrogen carrier gas reduces analysis times by a factor of 1.4 and 3.7 compared to helium and nitrogen, respectively.

The carrier gas linear velocity through the column is critical in determining how quickly an analysis will proceed, and also how efficiently the column will resolve the peaks. The choice of carrier gas linear velocity will often represent a compromise between speed and efficiency. Selection of a low  $u$  will deliver a relatively poor result and take a long time to do so; for this reason low velocities should be avoided. Operating at high velocities produces a chromatogram more rapidly but sacrifices some column efficiency. The optimum practical linear carrier gas velocity (OPGV) depends upon the carrier gas type, the column characteristics, the temperature, and the sample (and the column pressure drop – see below). Typical OPGVs are of the order of  $20\text{--}60\text{ cm s}^{-1}$ .

The optimum linear velocity for a capillary column depends on the pressure in the column because  $u_{\text{opt}}$  is proportional to the average diffusion coefficient, which varies inversely with pressure. Operation of a short wide-bore column at vacuum outlet conditions results in a significantly faster analysis than would occur if the same column was used under atmospheric outlet pressures. Mass spectrometry (MS) has made vacuum GC very easy to implement, since the mass spectrometer provides both detection and a source of vacuum. Vacuum GC can be achieved practically by incorporating a restriction at the inlet end of a wide-bore capillary column, and interfacing the terminal end of the column directly into the MS. The function of the restriction is to deliver an optimal helium flow for the mass spectrometer, and it can be as simple as a short section of  $20\text{ }\mu\text{m}$  i.d. capillary (or a longer section of  $100\text{--}150\text{ }\mu\text{m}$  i.d. capillary). An optimal carrier gas velocity of  $\sim 90\text{--}100\text{ cm s}^{-1}$  can be expected for a  $10\text{ m} \times 50\text{ }\mu\text{m}$  column with a restriction at the inlet, and a speed gain of a factor of 3–5 times can easily be obtained.

**Temperature programming requirements for fast-GC** An optimal temperature program rate for fast-GC will deliver the best separation in the shortest possible time. Method development and optimization can be achieved using a chemometric approach such as central composite design. This type of approach is suitable for the development of a method for the analysis of a sample of limited complexity, but optimization procedures for temperature programs become more complex, more time consuming, and may offer limited success for samples containing a greater number of components (e.g.,  $>20$ ).

A recent study determined that a generally applicable optimum temperature program rate offered a suitable compromise between peak capacity, separation power, and analysis time. This concept uses  $t_{\text{M}}$  as a fundamental time unit, and showed that a temperature

**Figure 4** Fast-GC chromatogram of kerosene using a method developed using the  $10^\circ\text{C}/t_{\text{M}}$  criterion.

program rate of  $10^\circ\text{C}/t_{\text{M}}$  was generally applicable. A typical fast-GC chromatogram of kerosene using a  $10^\circ\text{C}/t_{\text{M}}$  criterion for new method development is given in **Figure 4**. Ramp rates significantly faster than  $10^\circ\text{C}/t_{\text{M}}$  will not allow for sufficient partitioning time in the stationary phase for the effective use of the column. This optimization approach arose from the concept of method translation described next.

**Method translation** Although there will often be a requirement to create entirely new fast-GC methods, it will also be desirable in many circumstances to translate optimized methods for conventional columns to narrow bore columns. The aim of method translation is to vary components (columns, carrier gases, detectors, etc.) and parameters (pressures, temperature programs, etc.) of a method in a way that maintains the peak elution pattern. In other words, method translation yields a scaled version of the original chromatogram. A common mistake in attempting to gain analysis speed is to only apply a more rapid temperature program. Since relative retention (and elution order) of solutes depends on temperature, the application of a more rapid temperature program can cause peaks to shift relative to one another, and valuable well-known fingerprint information can be lost. However, changes in heating rates, and durations of temperature plateaus, column dimensions, carrier gas type, and pneumatic conditions are translatable changes. Changes in stationary phase type and phase ratio are not translatable. A fast-GC analysis using a smaller diameter column is given in **Figure 5**, where the slower GC analysis using a more conventional diameter column is overlaid to illustrate the effectiveness of method translation in providing a scaled version of the original chromatogram. Method translation software is available at no cost (GC Method Translation Freeware).

## Instrument Requirements for High-Speed GC

### Carrier Gas

The important role that the carrier gas linear velocity plays in determining column efficiency has been discussed above. This is distinctly different to the column flow rate, which is important in determining the suitability of the column with the GC system inlets and detectors. Peak distortion can result if the column flow rate is too low or too high. Long, smaller-diameter columns require high column head-pressures to provide an appropriate carrier gas flow rate. Conversely, short columns call for a low, but very precise head pressure, which can cause difficulties in maintaining stable system operation. The low flow rates in capillary GC are suitable for use with mass spectrometric detection, which operates most effectively up to a maximum rate (typically up to a few milliliters per minute), after which the detector performance begins to deteriorate. Detectors such as electron capture detector (ECD) or flame ionization detector (FID) will require a make-up flow for proper functioning. Modern instrumentation design generally addresses the typical problems; for example, a new chromatograph can be equipped with electronic pressure control units operating up to 10–12 bar, providing sufficient pressure to efficiently operate a 10 m × 50 μm or 20 m × 100 μm capillary column.

Whilst hydrogen is the most appropriate carrier gas choice in most cases for fast-GC, safety concerns are a deterrent to some laboratories. However, modern chromatographs incorporate safety features to reduce the risk of H<sub>2</sub> leaks and the risk of explosion is inherently very low.

### Sample Introduction

The general requirements for sample introduction in fast-GC include the accurate delivery of a small injection size, typically using a fast injection device. The effectiveness of the sample introduction system will be measured by its ability to deliver a sufficiently narrow injection band. In 1966, Sternberg described how column performance is degraded by the design of the injection port, dead volume, and surface activity in the flow lines, detector cell design, and electronic time constants. These effects are summarized in eqn [9], where the subscript 'o' denotes all contributions other than the injector and the column:

$$\sigma^2 = \sigma_{\text{col}}^2 + \sigma_{\text{inj}}^2 + \sigma_o^2 \quad [9]$$

Since on-column peak variance is generally low in fast-GC, the contribution of the injector to the total peak variance can become significant, so the injector must be able to deliver a suitably narrow injection bandwidth. Split injection is the most common method of sample introduction for fast-GC. This technique is the only sample introduction method that allows injection at any column temperature. This can be contrasted with on-column injection that requires the column to be below the solvent boiling point at the time of sample introduction, and splitless injection that usually requires cooling to achieve cold trapping or solvent effects. Using very fast split flow rates can produce very sharp initial bands; split flows of 21 min<sup>-1</sup> have been shown to provide injection bandwidths in the millisecond range. However, since the typical flow rate through narrow bore columns is low, it results in a very high split ratio, which can cause irregular sample transfer into the column, and irreproducibility with samples containing analytes at widely differing concentration. The use of a very high split ratio also increases the limit of detection. The requirement for very high split ratio can be relaxed by using temperature programmed GC because thermal focusing at the initial oven temperature may refocus the input band.

In circumstances where injection cannot produce sharp enough initial bands, they will need to be focused following the injection and immediately prior to the commencement of the analysis. This can be achieved by the use of specialized cold-traps, using liquid nitrogen or carbon dioxide to cause cryogenic

focusing of the initial band. An on-column thermal desorption modulator, such as that developed by Phillips and co-workers in the late 1980s, also offers a technically simple and reliable method for sample introduction into smaller internal diameter columns. Another contemporary approach for sample introduction in fast-GC includes the use of fast rotating microinjection valves (providing injection times  $<100$  ms), which perform very fast injections to minimize injection band broadening. A method described by Sacks employed cryotrapping of injected sample, which was then very rapidly thermally desorbed at  $1000^{\circ}\text{C s}^{-1}$  and back-flushed into the capillary column. An injection bandwidth of a few milliseconds was reported.

### Oven

The main requirement of the oven for fast temperature programmed GC will be its ability to provide rapid linear temperature gradients. The earlier section on temperature programming requirements for fast-GC described the concept of using  $t_M$  as time unit. Here, we shall put this concept into practice to illustrate the stresses that this imparts on the instrument. As a first example, consider a  $10\text{ m} \times 100\text{ }\mu\text{m}$  column provided with 200 kPa head pressure ( $\text{H}_2$ ) at  $60^{\circ}\text{C}$ . This column will have an average linear carrier gas velocity of  $\sim 55\text{ cm s}^{-1}$ , giving  $t_M$  of  $\sim 0.303$  min. Most instruments should easily deliver a temperature program of  $33^{\circ}\text{C min}^{-1}$  (i.e.,  $10^{\circ}\text{C}/t_M$ ; see above). However, if a 2 m column of the same internal diameter was used,  $t_M$  (for  $55\text{ cm s}^{-1}$ ) would be  $\sim 0.0606$  min. Whilst temperature programming at  $33^{\circ}\text{C min}^{-1}$  would still provide a faster chromatogram than the previous experiment, the  $10^{\circ}\text{C}/t_M$  approach would suggest that a temperature program rate of  $165^{\circ}\text{C min}^{-1}$  would still render a chromatogram with sufficient peak capacity and separation power. Clearly, this chromatogram would be generated in a greatly reduced time, but the inability of most instruments to achieve such a high temperature program rate would limit this application.

Another important consideration of the GC oven in fast-GC analysis is the cool-down period. Indeed, the total analysis time should take into consideration the GC runtime, the oven cool-down period, and also the sample preparation step. Automated sample preparation, often in large batches, is becoming increasingly popular, reducing this part of the total analysis time. Thus, maximum time efficiency will require the shortest possible oven cool-down and equilibration time. Modern GC equipment is constructed of lightweight material to assist in heat transfer from the oven walls to the oven air, which is

expelled by an efficient ventilation system. Some chromatographs are fitted with a cryogenic cooling system to rapidly decrease the oven temperature. The use of a device commonly referred to as a 'pillow', which can be inserted into the oven cavity to reduce the size of the oven, is also effective for fast-GC. Ultimately, a series of 2 min analyses with 5 min cool-down periods will always take less time than a series of 30 min analyses with 5 min cool-down periods, so the cool-down period should generally not be considered the rate determining step.

### Considerations for Detection

Peaks generated by fast GC are no different to measure than other chromatographic peaks, except that they are narrower, and a high detector sampling frequency will be required to measure very narrow peaks accurately. Data points from 10 to 20 per  $\omega_b$  is generally considered a sufficient number; however, it has been suggested that this number should be far greater to reduce measurement uncertainty for asymmetric peaks.

FID detection can be routinely performed using data acquisition rates in excess of 100 Hz, and other detectors such as the  $\mu$ -ECD offer suitably rapid data acquisition for fast-GC.

### Mass Spectrometry

Scan speed, sensitivity, and useful dynamic range affect the compatibility of a mass spectrometer with a high-resolution chromatograph. Improvements in GC, particularly in the direction of high-speed GC have led to a strain in the relationship between residence time of the sample in the ion source and mass spectral scan time. Quadrupole and ion-trap mass spectrometers are most commonly used for GC-MS. The physical laws governing mass selection processes limit the ability of these detectors to provide suitable detection in fast-GC. For example: a quadrupole MS passes ions of various  $m/z$  (one  $m/z$  at a time) to the detector by simultaneously ramping direct current (DC) and radio frequency (RF) voltages carried by four quadrupole rods. To ensure maximum transmission of the selected ions, the RF and DC voltages should not change during the transit time of an ion through the quadrupole. Contemporary MS instruments are capable of mass scanning rates of around  $4000\text{--}7000\text{ u s}^{-1}$ . Thus, for a full scan mass range of  $50\text{--}350\text{ u}$ , the maximum spectral acquisition rate would be expected to be less than 10–20 spectra per second (including an interscan period).

Time-of-flight (TOF) MS does not suffer the same speed limitations of the previously mentioned instrument types, because the spectral acquisition rate is essentially determined by the transit time of the

heaviest ion in the mass spectrum. The major advantage TOF-MS has is that a complete spectrum is produced serially at the detector for each pulse of ions from the source. Considering an ion of 800 u and 2 keV acceleration potential will take  $\sim 90 \mu\text{s}$  to travel from the source to the detector in a 2 m flight tube, it is possible to acquire a full spectrum from 0 to 800 u every  $90 \mu\text{s}$ . This equates to a spectral acquisition rate of  $\sim 11\,000$  spectra per second. Fast-GC-TOF-MS instruments will become more widespread in the coming years. Whilst fundamental principles of mass analysis govern the scan speed of quadrupole and ion trap instruments, the usable spectral acquisition rate of TOF analyzers are only determined by the method of data collection and storage.

## Introduction

The principal function of the gas chromatograph is to provide those conditions required by the column for achieving a separation without adversely affecting its performance. Operation of the column requires a regulated flow of carrier gas; an inlet system to vaporize and mix the sample with the carrier gas; a thermostatted oven to optimize the temperature for the separation; an online detector to monitor the separation; and associated electronic components to control and monitor instrument conditions, and to record, manipulate, and format the chromatographic data. Individual instruments differ mainly in their control functions (whether software-based or mechanical), ease of portability (designed for laboratory, field, or process applications), level of automation, and flexibility (number of supported options). The primary support functions of a typical gas chromatograph can be broken down into pneumatic, thermal, and electronic system components as illustrated in Figure 1.

## Pneumatic Systems

Gas supplies are required for the carrier gas, and depending on the instrument configuration, perhaps also for the detector, for operating pneumatic controls such as switching valves, and for providing automatic cool down by opening the oven door. Gases are normally provided from pressurized cylinders, although compact generators capable of providing air or nitrogen filtered from the atmosphere

## Introduction

The principal function of the gas chromatograph is to provide those conditions required by the column for achieving a separation without adversely affecting its performance. Operation of the column requires a regulated flow of carrier gas; an inlet system to vaporize and mix the sample with the carrier gas; a thermostatted oven to optimize the temperature for the separation; an online detector to monitor the separation; and associated electronic components to control and monitor instrument conditions, and to record, manipulate, and format the chromatographic data. Individual instruments differ mainly in their control functions (whether software-based or mechanical), ease of portability (designed for laboratory, field, or process applications), level of automation, and flexibility (number of supported options). The primary support functions of a typical gas chromatograph can be broken down into pneumatic, thermal, and electronic system components as illustrated in **Figure 1**.

## Pneumatic Systems

Gas supplies are required for the carrier gas, and depending on the instrument configuration, perhaps also for the detector, for operating pneumatic controls such as switching valves, and for providing automatic cool down by opening the oven door. Gases are normally provided from pressurized cylinders, although compact generators capable of providing air or nitrogen filtered from the atmosphere

**Figure 1** Schematic diagram of the principal components of a gas chromatograph. Bold lines indicate the path taken by sample and carrier gas resulting in the production of the chromatogram. The thin lines represent support and control functions.

and hydrogen electrolytically from water are becoming increasingly popular. Each gas cylinder is fitted with a two-stage regulator for coarse pressure and flow control. To minimize contamination of the chromatograph high-purity gases are used together with additional chemical and/or catalytic gas purifying devices. The carrier gas flow is directed through a particle filter and charcoal and molecular sieve traps to remove volatile organic compounds and moisture, and then through an additional chemical trap to remove oxygen. Oxygen causes degradation of some stationary phases, shortens filament lifetime for thermal conductivity detectors, and yields unstable baselines with the electron-capture detector. Water shares some of the same properties as well as being a strong deactivating agent that can cause poor reproducibility of retention times in gas-solid chromatography. Support gases for detectors and valve operation, etc., usually require less intensive purification depending on how they are used.

The carrier gas and support gases then enter the pneumatic section of the gas chromatograph, in which pressure regulators, flow controllers, and, perhaps, additional gas purifying traps and particle filters are housed in a thermostatted box. Fuel gases required by flame-based detectors need only be coarsely controlled by, for example, a calibrated restrictor or needle valve. In most early instruments carrier gas flow control was widely used for packed columns while pressure control was more common for open tubular columns. Since the early 1990s, electronic pneumatic control devices have become increasingly popular and are common on all modern keyboard controlled instruments. Electronic pressure control uses a solid-state pressure sensor and an electronically controlled proportional valve to achieve precise closed loop control of the column inlet pressure. The use of sensors and valves allows operation at constant mass flow independent of the column flow resistance, constant pressure, and pressure program modes under full software control. Typical electronic flow controllers with a range of  $1\text{--}500\text{ ml min}^{-1}$  are capable of an accuracy of  $\pm 1\text{--}2\%$  full scale and a repeatability of the set point of  $\pm 0.2\%$  or better.

## Thermal Zones

The column oven is essentially an insulated box of sufficient size to allow comfortable installation of the longest columns and any accessory equipment normally used. The oven is heated by electrical heating elements arranged around a powerful circulatory fan. Microprocessors, sensors, and proportional heating

networks are used to maintain a stable isothermal temperature and to control the initial temperature lag, the linearity of the program rate, and the final temperature overshoot in temperature programmed operation. A temperature stability of  $\pm 0.2^\circ\text{C}$  in time and  $\pm 1.0^\circ\text{C}$  in space are typical specifications for modern instruments. Poor column temperature stability is a source of peak distortion or splitting and retention time variation with open tubular columns.

Separations in gas chromatography are carried out within the temperature limits from about  $-100^\circ\text{C}$  to  $450^\circ\text{C}$ . Purpose-built instruments are usually required for high-temperature operation between  $375^\circ\text{C}$  and  $450^\circ\text{C}$ . Subambient temperature operation using the boil over vapors from liquid nitrogen or carbon dioxide for cooling is available as an option for standard instruments. The oven temperature is adjusted using an electrically controlled solenoid valve to pass coolant into the oven where it is mixed with air and then circulated at high velocity.

Typical linear temperature program rates are  $0.1\text{--}50^\circ\text{C min}^{-1}$ , selectable in incremental steps. Rapid cool down of the column oven is achieved by automated opening of the oven door or flaps to allow heat dissipation. Fast gas chromatography requires heating and cooling rates much faster than those specified for standard operation. Resistive heating using a tube within a tube or a wire adjacent to the column configuration are the favored options.

Other thermal zones, which should be thermostatted separately from the column oven, include the injector and detector modules. These are generally insulated metal blocks fitted with cartridge heaters and controlled by sensors located in a feedback loop with the power supply. Detector blocks are usually maintained at a constant temperature while requirements for injectors may be different, and may include provision for temperature programmed operation.

## Sample Handling Devices

Gas chromatography is used to separate gases, vapors of volatile compounds supported in a gas matrix, liquids, and solids. Solid samples are usually dissolved in a suitable solvent and handled as for liquid samples. Insoluble solids can be analyzed indirectly by separation of the decomposition products generated by controlled pyrolysis. Compounds in the vapor phase are often separated after concentration on solid sorbents or cryotrap followed by rapid heating to release the organic vapors into the column. Thermal desorption interfaces are widely used for the analysis of trace organic volatiles in air or generated by headspace and gas purging devices.

## Microsyringes

Microsyringes are commonly used for introducing liquid samples into a gas chromatograph. A typical microsyringe consists of a calibrated glass barrel with a close fitting metal plunger, which is used to dispense a chosen volume of sample by displacement through the syringe needle. Gas-tight syringes, some with a valve mechanism to close the passageway to the needle, are available for injecting gases and vapors.

Although microsyringes are considered indispensable for injection of liquids, they do present certain difficulties. The accuracy of injection depends on the rate of sample introduction, syringe dead volume, heating of the syringe needle by the injector, and sample handling techniques. Packed columns accommodate relatively large sample volumes (e.g., 1–5  $\mu\text{l}$ ) and are forgiving of poor injection techniques. The injection of comparatively small volumes, typically 0.1–2.0  $\mu\text{l}$ , is more common for open tubular columns. In this volume range needle dead volumes and backflushing of sample past the plunger can represent significant contributions to poor injection precision. Discrimination of sample components is possible with hot vaporizing injectors with open tubular columns. The sample leaves the syringe and enters the vaporizer as a stream of droplets, formed by the movement of the plunger and by evaporation of the remaining sample from the syringe needle. It is at this evaporation stage that discrimination is most likely to occur; the solvent and more volatile sample components distill from the syringe needle at a greater rate than the less volatile components.

## Gas Sampling Valves

Rotary valves with six, eight, or more connection ports, operated manually or automated through electronic or pneumatic controllers, are commonly used for introducing gases and volatile compounds into all column types as well as for column switching applications in multidimensional gas chromatography. Rotary valves are also used for large volume sample introduction in on-column injection and as an interface for coupling liquid chromatography to gas chromatography.

The gas sample to be injected is isolated in a sample loop of defined volume at a known temperature and pressure (usually ambient). Subsequent rotation of the valve body causes the carrier gas to sweep the entire contents of the sample loop onto the column. External sample loops with defined volumes in the range 0.5  $\mu\text{l}$  to 5 ml are commonly used. Valves with internal sample loops are available for handling small sample volumes of 0.2–5  $\mu\text{l}$ . Multiport valves with two or more sample loops can be used for

simultaneous sampling of several sources or for continuous sampling of a single source by storing individual samples in different loops for sequential analysis at a later time. Gas sampling valves are usually mounted in the column oven, in a separately heated adjacent oven, or external to the column oven and connected to the column by a short length of capillary tubing. For the most accurate work it is recommended that the injection valve is thermostated in its own oven.

## Liquid Sample Inlets

### Packed Column

Liquid samples are introduced by a microsyringe through a silicone rubber septum into a glass liner or the front portion of the column, which are heated and continuously swept by the carrier gas, **Figure 2**. When injection is made in the on-column mode, the column is pushed right up to the septum area and the column end within the injector is packed with glass wool. Whichever technique is used, the injector must

**Figure 2** A flash vaporization inlet for packed column gas chromatography. (Reproduced with permission from LCGC, vol. 15, no. 11, Nov. 1997, 1024p.)

have sufficient thermal mass to rapidly vaporize the sample. The incoming carrier gas is usually preheated by directing its flow through a section of the injector block to avoid possible condensation of the vaporized sample upon mixing with the cool carrier gas.

### Hot Split/Splitless

The classical hot split injector for open tubular columns, **Figure 3**, is an isothermal vaporizing injector, in which the evaporated sample is mixed with the carrier gas and divided between two streams of different flow, one entering the column (carrier gas flow) and the other vented to the outside (split flow). The vaporization chamber is typically a stainless steel tube lined with a removable glass liner to minimize sample contact with hot reactive metal surfaces. In the forward-pressure configuration the inlet pressure is controlled by a pressure regulator in front of the inlet and the split flow by an on/off solenoid valve and a fixed restrictor or needle valve at the split vent exit from the inlet. The backpressure configuration uses a flow controller to establish the total flow of carrier gas to the inlet and a backpressure regulator in the split vent line to control the inlet pressure.

**Figure 3** A hot split/splitless injector for open tubular column gas chromatography. (From Tipler A and Ettre LS (1997) *The Prevent System and its Application in Open-Tubular Column Gas Chromatography*. Norwalk: Perkin-Elmer Corporation.)

Liquid samples are introduced into the vaporization chamber by syringe through a septum or airlock. An auxiliary flow of gas is used to purge septum bleed products and contaminants away from the vaporization chamber. Appropriate column loads are usually achieved by injecting sample volumes of 0.2–2.0  $\mu\text{l}$  with split ratios between 1:10 and 1:1000.

For mixtures containing sample components of unequal volatility split injection discriminates against the less volatile sample components due to selective evaporation from the syringe needle and from incomplete sample vaporization and inhomogeneous mixing of sample vapors with the carrier gas in the vaporization chamber. Sample evaporation generates an instantaneous pressure pulse and rapid change in the viscosity of the carrier gas sample mixture, altering the flow of gas between the column and split line in an irreproducible manner. Condensation of sample vapors in the cooler column inlet creates a zone of reduced pressure that sucks in further amounts of sample vapor. In most cases the sample arrives at the split point only partially evaporated as a mixture of vapor and droplets of various sizes. The sample components are unlikely to be evenly distributed between the vapor and liquid phases, the latter being split to different extents and resulting in discrimination. Discrimination is the principal cause of difficulties in quantitative analysis.

Splitless injection uses a similar injector design to split injection but is more suitable for quantitative analysis of trace components in dirty samples, such as biological and environmental extracts. Conversion of a split to a splitless injector usually requires no more than the installation of a different liner and the interruption of the split flow at the start of the injection using a solenoid valve located in the vent line. The split flow is restarted only at the end of the sampling period. Since the flow of gas through the vaporization chamber is normally the same as the carrier gas flow for the column the transport of sample vapors to the column is relatively slow. During the initial rapid evaporation of the sample there is minimal transfer of vapors into the column. Consequently, the volume of the injection liner must be large enough to hold the entire volume of vapor produced by the evaporated sample. A liner volume of  $\sim 1$  ml is sufficient to hold up to about  $\sim 0.5$ – $2$   $\mu\text{l}$  of vaporized solvent. Splitless inlets equipped with electronic pneumatic control allow high inlet flows at the start of injection, followed by a rapid reduction of pressure to a value required to provide the desired column flow rate. This minimizes the backflusing of sample vapors out of the injection liner during injection. It also allows larger sample volumes, up to 5  $\mu\text{l}$ , to be introduced with a standard liner.

Sample transfer to the column by splitless injection requires a comparatively long transfer time, from several seconds up to a few minutes, relying on cold trapping and/or solvent effects to refocus the sample at the column inlet. The sample transfer time is roughly equivalent to about twice the time required by the carrier gas to sweep out the volume of the vaporization chamber. Since the sample vapors are continually diluted with carrier gas, and some sample vapors accumulate in areas poorly swept by the carrier gas, complete sample transfer is difficult to achieve. At the end of the sample transfer period, the split flow is re-established to purge the inlet of remaining solvent vapors.

### Direct

Direct injection is used with wide bore capillary columns ( $\geq 0.32$  mm) operated at relatively high flow rates of  $5\text{--}15\text{ ml min}^{-1}$ . The injector consists of a thermostatted hot vaporization chamber with a direct connection between the liner and the column, **Figure 4**. Typically, a double gooseneck liner is used with the column fixed to the constriction at the bottom end (the seal is usually made between the polyimide outer coating of the column and the inner glass surface of the liner). Using a liner with a single

**Figure 4** Suitable liners for direct splitless (left) and on-column (right) injection onto wide bore open tubular columns.

restriction at the top end where the column seal is made allows the injector to be converted into a hot on-column injector. In this case, the restriction acts as a base for the column seal and a needle guide to direct the syringe needle into the column or a retention gap connected to the column. Injection volumes are typically in the range  $2\text{--}8\text{ }\mu\text{l}$ . A hot split/splitless injector can be converted to a direct injector by changing the liner and disabling the split vent.

### Programmed Temperature Vaporizer

The programmed temperature vaporizer (PTV) injector, **Figure 5**, can be used as a split/splitless injector for samples of normal volume or as a large volume injector. The PTV vaporization chamber is about one-tenth the size and of lower thermal mass than chambers employed for classical hot split/splitless injection. This allows the vaporization chamber to be rapidly heated by either direct or indirect resistive heating, using cartridge heaters or circulated hot air. Cooling can be performed using cold air, a Peltier element, or expanding carbon dioxide or

**Figure 5** Programmed temperature vaporizer injector. (From Hinshaw JV and Seferovic W (1986) Programmed-temperature split-splitless injection of triglycerides: comparison to cold on-column injection. *Journal of High Resolution Chromatography* 9: 69–77.)

liquid nitrogen vapors. Compared with hot split/splitless injection, the PTV injector greatly reduces discrimination of less volatile compounds, minimizes thermal degradation because of the shorter sample residence time at elevated temperatures, and is adaptable to the introduction of a wide range of sample volumes. Large volume injections are of particular interest since they allow an increase in detected peak signals, important for trace analysis. The PTV injector is also more tolerant of involatile matrix components and affords good quantitative accuracy. The PTV is a useful interface for coupling a number of sample preparation methods to gas chromatography such as high-performance liquid chromatography, supercritical fluid extraction, solid-phase extraction, and thermal desorption.

For normal split injection, the sample is introduced at a temperature below the solvent boiling point with the split exit open. Shortly after withdrawal of the syringe needle the injector is rapidly heated to a temperature high enough to ensure rapid evaporation of the least volatile sample components. Discrimination effects, which are common for hot vaporizing injectors, are virtually eliminated and the sample split ratio and split flow ratio are similar.

For cold splitless injection, the sample is introduced into the vaporizing chamber at a temperature close to the solvent boiling point with the split vent closed. Shortly after sample introduction, the injector is rapidly heated to the temperature required to transfer the sample into the column, and the vaporization chamber purged of solvent residues by opening the split vent. Similar to hot splitless injection, cold trapping and solvent effects are employed as refocusing mechanisms.

For large volume injection, the PTV injector can be operated as a cold split injector with solvent elimination or as a hot splitless injector with vapor overflow. Splitless injection with vapor discharge is not as popular as the above methods. In this case, solvent elimination is comparatively slow and the maximum volume of sample that can be introduced is only 20–30  $\mu\text{L}$ .

In cold split injection, the sample is introduced into the injector at a temperature below the solvent boiling point with the split vent open. The solvent is concurrently evaporated in the glass insert and swept through the split vent by the carrier gas. When evaporation of the solvent is complete, the split vent is closed and the injector rapidly heated to the temperature required to vaporize the sample and transfer it to the column. Large sample volumes can be introduced in several increments, or more elegantly, with a speed-controlled injector. Maximum sample volumes are  $\sim 20 \mu\text{L}$  (1.2 mm ID liner) or  $150 \mu\text{L}$  (3.4 mm ID liner)

using a single injection or  $\sim 1 \text{ mL}$  using speed-controlled injection. During solvent elimination, cold trapping and solvent effects are responsible for retention of the analytes within the liner.

For hot splitless injection with vapor overflow, the sample is injected rapidly into the lower part of a packed liner at a temperature well above the solvent boiling point. Violent evaporation causes most of the expanding solvent vapor and volatile sample components to escape through the septum purge outlet. Solutes of low volatility are retained in a low-temperature zone created by the evaporating solvent. After solvent elimination the temperature of the retaining zone rapidly returns to the injector temperature transferring the analytes to the column. Tenax or silanized glass wool is commonly used as packing material to increase the retention power of the liner. Even so, semivolatile analytes are difficult to trap quantitatively.

### **Cold On-Column**

Cold on-column injection employs the direct introduction of the liquid sample into the oven-thermostatted column inlet or retention gap (precolumn) without prior vaporization in a heated external chamber. The sample is subsequently vaporized from the liquid film formed in the column inlet or retention gap. Discrimination is virtually eliminated and quantification of components of different volatility is facilitated. On-column injection is easily automated using a wide bore retention gap connected to the separation column and is easily adapted to the introduction of large sample volumes. On-column injection is not suitable for the introduction of samples containing significant amounts of involatile matrix components that accumulate at the column inlet increasing its retentive power and activity.

On-column injection requires special syringes with small external diameter needles (since at the point of sample release the needle must reside within the column) or a wide bore retention gap if standard size needles are used. The injector scaffold is designed to afford a mechanism to guide the syringe needle into the column, for positioning the needle at the correct height within the column, and for sealing the needle passageway, or at least restricting the flow of carrier gas out through the syringe entry port. Circulating air is used in some designs to control the temperature of the needle passageway to avoid solvent evaporation.

Sample volumes of  $\sim 0.2\text{--}1.5 \mu\text{L}$  can be injected rapidly into the column. For larger volumes of up to  $\sim 50 \mu\text{L}$  a retention gap is required to avoid peak distortion by band broadening in space. A retention

**Figure 6** A typical arrangement for large volume on-column injection with an early solvent vapor exit and retaining precolumn. AC = separation column; RP = retaining precolumn; and RG = retention gap.

gap combined with an early solvent vapor exit and optional retaining precolumn, **Figure 6**, is suitable for injections up to  $\sim 100\ \mu\text{l}$  with larger volumes introduced at a controlled speed using partial concurrent evaporation. To avoid loss of volatile analytes the solvent vapor exit must be closed just before the last drop of solvent evaporates. A number of methods are available for this critical step, such as monitoring the effluent leaving the vapor exit with a flame or by observing the restoration of the carrier gas flow at the completion of the evaporation step. Quantitative accuracy and precision ( $<1\%$  RSD for automated injectors) is excellent using internal standards to correct for differences in volume delivery.

### Retention Gaps

Retention gaps are column inlets with a reduced retention power compared with the separation column. They function as guard columns to protect the separation column from contamination by nonvolatile residues; wide bore retention gaps permit the use of autoinjectors with standard syringe needles; and retention gaps facilitate the injection of large sample volumes. Most retention gaps are simply different lengths of uncoated fused-silica tubing, deactivated by the same techniques as those used for column preparation, as required, to modify their solvent

compatibility or surface activity. It is important that the solvent wet the retention gap in order to produce a film of liquid over the column wall to facilitate solvent evaporation. Solutes migrate through the retention gap at temperatures well below those required to cause elution from the separation column. Thus, they arrive at the entrance to the separation column at a temperature too low for significant migration and accumulate there until a temperature is reached at which migration starts. Retention gaps are essential when sample volumes greater than  $\sim 5\ \mu\text{l}$  and up to several hundred microliters are injected.

### Vapor Sample Inlets

A number of important sample preparation techniques rely upon gas extraction or the analysis of samples in the gas phase. These samples usually contain low concentrations of volatile analytes and higher concentrations of water vapor in a low molecular weight gas or air. Direct sample introduction by syringe or valves is only suitable for small volumes of relatively concentrated samples. More common sample introduction methods involve analyte accumulation by sorbent or cryogenic trapping followed by vaporization in the presence of a flow of gas to transport the analytes to the column. Important

automated sample introduction methods based on sorbent or cryogenic trapping include static and dynamic headspace (purge-and-trap) and solid-phase microextraction. In addition, rapidly heated cryogenic traps provide suitable inlets for fast gas chromatography and interfaces for coupled-column gas chromatography.

### Thermal Desorption

Typical sorbents used for analyte accumulation are porous polymers (e.g., Tenax), graphitized carbon blacks, and carbon molecular sieves, and in special cases inorganic oxides (e.g., silica gel). These are packed into stainless steel or glass tubes of different dimensions. Stainless steel tubes of 89 mm  $\times$  5 mm ID and 6 mm OD (volume  $\sim$ 3 ml containing 0.2–1.0 g of sorbent) or glass tubes 89 mm  $\times$  4 mm ID and 6 mm OD (volume  $\sim$ 2 ml) are considered standard sizes for compatibility with commercial thermal desorption devices. The trapped analytes are transferred to the column by thermal desorption at the chosen temperature using resistive heating or cartridge heaters housed in a heating block around the sampling tube. The time required for complete desorption is  $\sim$ 5–15 min with a purge gas flow of 30–50 ml min<sup>-1</sup> in the opposite direction to the sample flow employed for trapping. The slow desorption kinetics and high purge gas flow rates are compatible with packed columns allowing direct transfer with cold trapping by the stationary phase providing band focusing. For open tubular columns, a two-stage desorption process is generally required. The second accumulation trap is either a small-scale sorbent trap or cryogenic trap. Small-scale sorbent traps contain less than 100 mg of sorbent and have a low thermal mass allowing rapid heating ( $>35^\circ\text{C s}^{-1}$ ) to improve the band shape of transferred analytes. Desorption from the small-scale trap occurs at a flow rate of  $\sim$ 3 ml min<sup>-1</sup> with a desorption time of 1–5 min. A split flow between the trap and the column can be used to further adjust the sample concentration to the sample capacity of the column. Fully automated thermal desorption analyzers using a sequential tube sampler are available. Thermal desorption devices are usually designed as accessories to interface to a standard gas chromatograph with minimal modification. A thermostatted short length of deactivated fused silica or fused silica-lined stainless steel capillary tube acts as a transfer line terminated in a standard hot split/splitless injector.

### Cryogenic Traps

Volatile compounds can be retained by condensation if the temperature of the trap is below the dew point

for the compound. The trap can be an empty tube, a length of coated capillary column, or a packed tube containing a nonretaining material (e.g., glass beads). A nonretaining packing enhances condensation of volatile compounds while allowing rapid thermal desorption for their transfer to the column. Retaining materials afford higher trapping efficiency but slow desorption kinetics may result in poor chromatographic performance and low recovery of less volatile compounds.

Cold traps are often based on a tube within a tube design. The inner tube is a length of metal or fused-silica capillary surrounded by a wider metal or polymer tube through which cold gas is circulated around the annular space between tubes. The cold trap is usually located in the oven of the gas chromatograph. In most cases the fused-silica capillary inner tube is simply a portion of the column inlet or retention gap. The cold gas is obtained by passing gas through a tube contained in a cryostat or generated from the expanding vapors above liquid nitrogen or liquid carbon dioxide. The lowest temperatures that can be obtained are  $-196^\circ\text{C}$  to  $-180^\circ\text{C}$  for liquid nitrogen and  $-65^\circ\text{C}$  to  $-60^\circ\text{C}$  with liquid carbon dioxide. The low thermal mass of fused-silica capillary tubes allows rapid heating by the circulating air in the chromatographic oven, by circulating hot air from an external source, or by resistive heating of the outer tube surrounding the capillary. A feedback mechanism is used to control the flow of cryogen or hot air to allow accurate setting and cycling between set point temperatures with total automation.

Cryogenic traps are convenient accumulation and injection devices for fast gas chromatography and interfaces for coupled-column gas chromatography, where a heartcut sample is collected and focused from the first column, and reinjected into the second column. The main requirement for a cryogenic trap used in these applications is efficient accumulation over time with rapid injection of the collected analytes as a narrow pulse in both time and space. Commercially available systems using a capacitance discharge for heating provide injection bandwidths of 5–20 ms.

### Data Handling

Dedicated electronic integrators and personal computers with appropriate software for integration are routinely used for recording chromatograms. Computer-based systems are increasingly used since they can combine instrument control functions with chromatogram recording as well as providing electronic data storage. Computer-based systems also provide

flexible approaches for reporting results and for performing advanced data analysis techniques.

The continuous voltage output from chromatographic detectors is not a suitable signal for data handling by computer. The conversion of the detector signal to a computer-readable form requires an interface usually resident as an expansion card in the computer. The interface scales the detector output to an appropriate range, digitizes the signal, and then transfers the data to a known location in the computer. The original input signal is transformed into a series of voltages on a binary counter and is stored as a series of binary words suitable for data processing.

The important characteristics of the analog-to-digital conversion device are its sampling frequency, resolution, and range. The accurate recording of chromatographic peaks requires that at least 10 data points are collected over the peak width. For typical sampling frequencies of  $\sim 5$  Hz undersampling is usually only a problem in high-speed chromatography. Analog-to-digital converters used for chromatographic applications are usually autoranging, meaning that the detector signal is automatically divided into ranges so as to provide sufficient resolution near the baseline for peak detection while accurately registering the peak maximum for large signals. The resolution of the analog-to-digital converter is the smallest change in the analog signal that can be seen in the digital output (specified as the number of bits).

Converted data are usually averaged (bunched) to minimize storage space. Using the local peakwidth to determine the frequency of bunching creates uniform sampling density throughout the chromatogram. Long stretches of stable baseline are stored in one bunch represented by a single datum and the number of times it recurs. Stored data are initially smoothed and peak locations identified by a slope sensitivity function. Small peaks and baseline artifacts are removed using a threshold function or later by a minimum area reject function. Standard procedures may fail in the case of complex baselines, tailing peaks, or excessive peak overlap.

## Preparative Gas Chromatography

The most common types of preparative-scale gas chromatographs are based on packed-column technology. For simple separations, a short, wide packed column is generally used (e.g.,  $1\text{--}3\text{ m} \times 6\text{--}10\text{ cm ID}$ ). For difficult separations, higher column efficiencies are required, and long, narrow packed columns (e.g.,  $10\text{--}30\text{ m} \times 0.5\text{--}1.5\text{ cm ID}$ ) are used. Wide-bore packed columns cannot be coiled, and a purpose designed gas chromatograph is required for their use.

Typical sample volumes are  $0.1\text{--}10.0\text{ ml}$ , which are too large for injection by conventional techniques developed for analytical packed columns. In this case, an automated injector employing pneumatic transfer from a reservoir through a capillary restrictor, a pneumatic piston pump, or syringe pump is used. The injection process is controlled by time; a necessity owing to the limited capacity of injection block heaters to flash vaporize large sample volumes. To assist solvent vaporization, an evaporation device between the injector and column is often installed. This is often a tube, heated separately from the column oven, and packed with glass beads to increase its thermal capacity. Separations are usually performed isothermally since wide-bore packed columns are slow to respond to temperature changes. Separated components are detected by a thermal conductivity or flame ionization detector connected to the column via a splitter, so that only a few per cent of the total column flow is diverted to the detector. Collection of sample vapors in the carrier gas effluent is usually performed automatically, initiated by the detector signal. The exit from the detector splitter is led out through a side wall of the column oven and thermostatted to avoid condensation of the sample. Several methods are used to trap samples, including packed and unpacked cold traps, solution and entrainment traps, total effluent and adsorption traps, and electrostatic precipitators.

Open-tubular columns have a lower sample capacity than packed columns, but are useful for isolating a few milligrams of components from complex mixtures under high-resolution conditions. Automated sequencing of injection and fraction collection to accumulate sufficient sample is generally used. Short lengths of wide-bore capillary tubes, coated with a thick film of stationary phase, are efficient traps for room-temperature sample collection.

## Online Coupled LC–GC

**K Grob**, Official Food Control Authority of the Canton Zurich, Zurich, Switzerland

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Coupled high-performance liquid chromatography (HPLC)–gas chromatography (GC) is a two-step chromatography method: the sample is first separated by LC and then by GC. Usually LC serves as a sample preparation step for GC, but GC (particularly GC–MS) may also serve for the identification of LC peaks.

The development of online coupling of LC to GC was initiated in the early 1980s in the ‘mineral oil’ and ‘food analysis’ sectors. In 1989, a fully automated instrument was brought into the market by Fisons (Milan, Italy; today Thermo Electron), but was later discontinued.

### Reasons for Using LC–GC

The use of LC for sample preparation or preseparation has two main advantages: separation efficiency is much higher than with alternative chromatographic systems, such as conventional columns or solid-phase extraction (SPE), and control by standard LC detectors enables accurate control for cutting of the fractions to be transferred to GC. Hence, the technique offers outstanding selectivity for the analysis of trace components in complex samples or for group-type analysis of mixtures containing many similar components that are not separated by GC alone (e.g., mineral oil). The gain in efficiency for the preseparation is no longer substantial if broad mixtures of components are to be analyzed, which cannot be eluted from the HPLC column as sharp bands, e.g., pesticides.

### Offline versus Online LC–GC

The gain in separation efficiency is obtained irrespective of whether LC and GC are combined offline

or online. Offline LC–GC means collection of the LC fractions at the outlet of the column or detector, e.g., using autosampler vials that can directly be transferred to a GC autosampler. Introduction into GC usually requires a large-volume injection technique (100–500  $\mu$ l), because the amounts that can be injected into LC are usually not sufficient to obtain adequate sensitivity when only 1–2  $\mu$ l is injected into GC. The same techniques that are used for online transfer can be used for large-volume injection.

A routinely used example of offline LC–GC is the preseparation of complex migrates from food packaging materials (e.g., can coatings) by NPLC and GC–MS of the LC peaks. LC does not provide sufficient separation efficiency. GC–MS offers efficient additional separation, the ease of MS coupled to GC, and access to the large MS libraries. As identification is performed on only a few selected examples, online coupling offers little advantage.

When LC is coupled online to GC, far-reaching automation (sample preparation is integrated into the final analysis) enables the analysis of large numbers of samples with a minimum of manual interference. Highly accurate and reliable results can be expected, because losses are largely ruled out and the process is under almost complete control. For some types of analysis, exclusion of sample contamination from external sources is an additional important advantage.

### Typical Applications

Numerous applications for online LC–GC have been described for all important fields of analysis (summarized in Further Reading), but more than half of the methods applied concern mineral oil and edible oil or fat. A few are briefly outlined to illustrate typical strategies and conditions.

#### Aliphatic and Aromatic Hydrocarbons in Mineral Oil

As one of the first applications of online LC–GC in the early 1980s, mineral oil products were analyzed

The development of online coupling of LC to GC was initiated in the early 1980s in the ‘mineral oil’ and ‘food analysis’ sectors. In 1989, a fully automated instrument was brought into the market by Fisons (Milan, Italy; today Thermo Electron), but was later discontinued.

### Reasons for Using LC–GC

The use of LC for sample preparation or preseparation has two main advantages: separation efficiency is much higher than with alternative chromatographic systems, such as conventional columns or solid-phase extraction (SPE), and control by standard LC detectors enables accurate control for cutting of the fractions to be transferred to GC. Hence, the technique offers outstanding selectivity for the analysis of trace components in complex samples or for group-type analysis of mixtures containing many similar components that are not separated by GC alone (e.g., mineral oil). The gain in efficiency for the preseparation is no longer substantial if broad mixtures of components are to be analyzed, which cannot be eluted from the HPLC column as sharp bands, e.g., pesticides.

### Offline versus Online LC–GC

The gain in separation efficiency is obtained irrespective of whether LC and GC are combined offline

or online. Offline LC–GC means collection of the LC fractions at the outlet of the column or detector, e.g., using autosampler vials that can directly be transferred to a GC autosampler. Introduction into GC usually requires a large-volume injection technique (100–500 µl), because the amounts that can be injected into LC are usually not sufficient to obtain adequate sensitivity when only 1–2 µl is injected into GC. The same techniques that are used for online transfer can be used for large-volume injection.

A routinely used example of offline LC–GC is the preseparation of complex migrates from food packaging materials (e.g., can coatings) by NPLC and GC–MS of the LC peaks. LC does not provide sufficient separation efficiency. GC–MS offers efficient additional separation, the ease of MS coupled to GC, and access to the large MS libraries. As identification is performed on only a few selected examples, online coupling offers little advantage.

When LC is coupled online to GC, far-reaching automation (sample preparation is integrated into the final analysis) enables the analysis of large numbers of samples with a minimum of manual interference. Highly accurate and reliable results can be expected, because losses are largely ruled out and the process is under almost complete control. For some types of analysis, exclusion of sample contamination from external sources is an additional important advantage.

### Typical Applications

Numerous applications for online LC–GC have been described for all important fields of analysis (summarized in Further Reading), but more than half of the methods applied concern mineral oil and edible oil or fat. A few are briefly outlined to illustrate typical strategies and conditions.

#### Aliphatic and Aromatic Hydrocarbons in Mineral Oil

As one of the first applications of online LC–GC in the early 1980s, mineral oil products were analyzed

for aromatic and aliphatic compounds. As this was carried out mostly by mineral oil companies, hardly any details are public. A typical method (e.g., used for gasoline) uses a 2 mm i.d. normal-phase LC (NPLC) column packed with silica gel and pentane as the mobile phase. The paraffins are eluted at breakthrough and transferred to GC with about 200  $\mu$ l of eluent. Then the column is backflushed to recombine the aromatics to a narrow band, which is easily transferable to GC. Transfer into GC involves the retention gap technique (see below) to minimize the loss of volatile components: benzene and *n*-heptane are the limit.

### Mineral Hydrocarbons in Food

Many foods contain mineral oil material, either because of contamination from environmental sources or from packaging materials, lubricating oils, release agents, or as components in meat or eggs owing to the presence of paraffin oil or waste oils in the animal feed.

The final analysis occurs by GC-FID, because GC enables one to distinguish paraffins from natural and mineral origin and FID is the only detector with a practically constant response for all hydrocarbons. However, FID is not sensitive, and as the mineral paraffins form broad humps of unresolved components rather than a sharp signal, sensitivity tends to be low. The lack of selectivity is an additional problem, and the proof that the humps represent paraffins lies in a preseparation that allows only paraffins to reach GC. The final difficulty concerns blanks: laboratory glassware, fingers, etc. tend to release mineral paraffins, which renders manual sample preparation tedious. Online procedures eliminate most sources of sample contamination.

Paraffins are isolated from the sample matrix (edible oils or food extracts often containing much fat or oil) and separated from aromatics and olefins (e.g., sterenes from the raffination of edible oils) by NPLC. As it is difficult to maintain a high activity of silica gel to separate paraffins from olefins when large amounts of matrix material are injected, two columns are used: up to 30 mg edible oil or fat is injected onto a first column of 25 cm  $\times$  2 mm i.d. The hydrocarbons are transferred to a second column of the same dimension. The first column is backflushed with dichloromethane to remove the oil and other materials of the food extract. The second column only comes in contact with pentane as the mobile phase and nonpolar sample components, i.e. it maintains its high retention power for unsaturated components. Transfer of the fraction of about 400  $\mu$ l volume to GC mostly involves the retention gap

technique, using a 5–10 m  $\times$  0.53 mm i.d. uncoated precolumn fitted to a Y-piece branching to the solvent vapor exit and the separation column (see below). The detection limit of mineral paraffins in edible oils is 1–5 mg kg<sup>-1</sup>.

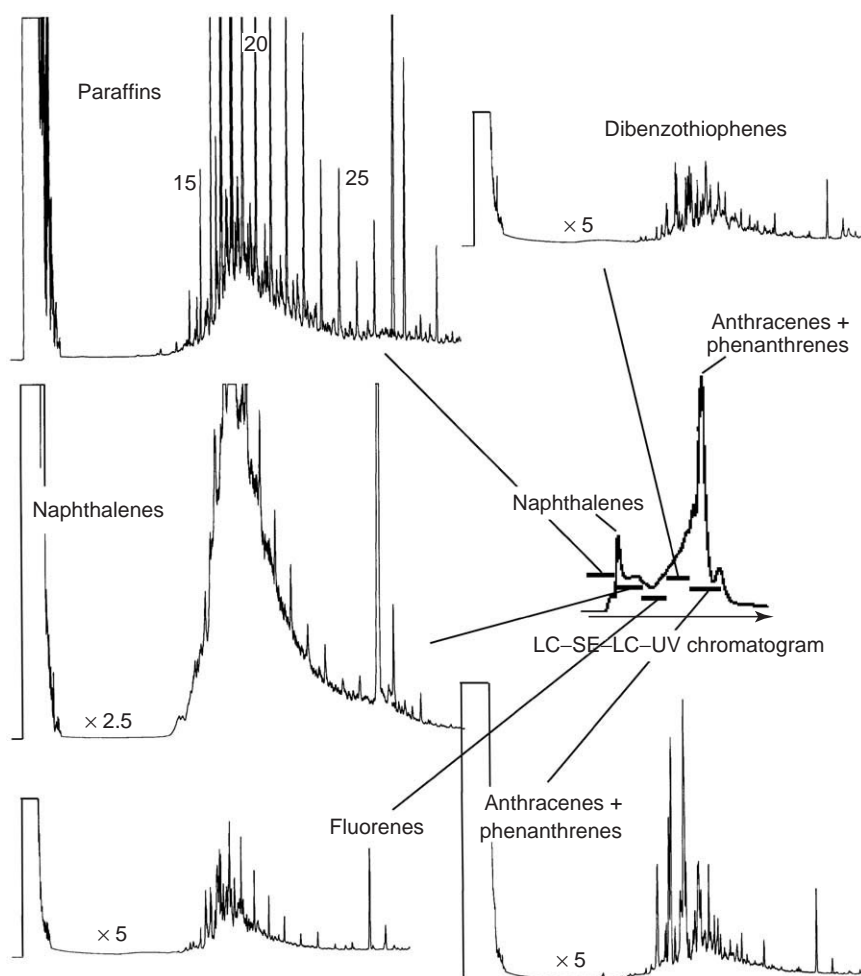

An online system for the analysis of aromatic hydrocarbons of mineral origin in foods, preseparating the aromatics by ring number, has been described. About 100 mg of oil or fatty extract is injected onto a 25 cm  $\times$  5 mm i.d. silica gel column. The resulting fraction of the hydrocarbons is too large (some 6 ml) and the mobile phase (pentane containing dichloromethane) is not suitable for the separation of the aromatics by ring number. Therefore, an online solvent evaporator consisting of a 40  $\times$  1 mm i.d. chamber packed with silica gel and connected to vacuum eliminates the solvent from the first LC step. The aromatics are transferred to an amino-derivatized silica gel column for separation by ring number before being introduced into GC. Mineral paraffins and aromatics in linseed oil contaminated from the jute bags used for transporting the linseeds are shown in Figure 1.

### Edible Oil Analysis

Some high-priced edible oils are adulterated by ever-more sophisticated methods, making it impossible to detect the added cheap oil by common control analysis (composition of fatty acids, triglycerides, or sterols). This compels the control to apply new and usually more complex analytical approaches. Since hundreds of samples have to be checked, a high degree of automation is a prerequisite for efficient control.

A first method simplified the classical analysis of the sum of free and esterified sterol: instead of saponification and tedious extraction from a soap solution, the sample is transesterified at ambient temperature and the mixture (containing the fatty acids as methyl esters) is preseparated by NPLC. The LC-UV chromatogram enables one to select the type of sterols ( $\Delta$ 5,  $\Delta$ 7, methyl-, dimethyl sterols) to be analyzed by GC (after online transfer through the loop-type interface).

Thousands of edible oils were checked for authenticity through the fingerprint of their 'minor components' (free sterols, sterol esters, wax esters, alcohols, tocopherols). The method primarily aimed at efficiency and automation. Some droplets of oil are silylated, diluted, and injected into NPLC. Through silylation, all the components of widely differing polarity are combined in a fairly narrow NPLC fraction eluted clearly before the triglycerides. This fraction is transferred to GC by the loop-type

**Figure 1** Perhaps the most complex LC-GC application used so far. LC-UV chromatogram from the second LC column (after isolation of the hydrocarbons on a large first LC column and eluent evaporation in a small online solvent evaporator): paraffins (with some carbon numbers indicated) and alkylated aromatics grouped by ring number. (Reproduced with permission from Moret *et al.* 1996.)

interface (all components are eluted from GC above 200°C).

Sterenes are dehydroxylated sterols, i.e., olefins, and result from raffination (bleaching, deodorization) or other strong heat treatment of edible oils. Their presence is used as an indicator of refined oil and their composition is fairly specific for a type of oil. For instance, the addition of refined vegetable oil to, e.g., nonrefined (extra virgin) olive oil is easily detectable in this way. The analysis presupposes high efficiency in the preseparation in order to isolate the sterenes from the (largely natural) paraffins and squalene with its many isomerization products. Even more detailed preseparation is required for a satisfactory resolution of the various types of sterenes, as needed for the identification of the nature of the oil the sterenes originate from. Two-step NPLC is applied, as described for the mineral paraffins in food, because only the second step provides reliable high

selectivity. As all compounds are rather high boiling, transfer involves the loop-type interface or other concurrent evaporation techniques. **Figure 2** shows the LC-LC-UV chromatogram of the sterenes from a refined rapeseed oil as well as the GC analysis of the fractions marked and numbered in the LC trace.

## LC for Coupled LC-GC

LC for coupling to GC is nearly exclusively in normal phase:

1. Transfer of normal-phase eluents to GC up to about 1.5 ml is easy.
2. At the concentrations required for the analysis, many sample matrices (mineral oil, edible oil, fat extracted from foods) are not soluble in reversed-phase media.
3. The solutes typically analyzed by GC are of rather low polarity and easy for NPLC.

4. Many samples are derivatized before injection into LC-GC, and such derivatives may not be compatible with water-containing eluents.

**Figure 2** LC–LC–GC analysis of the sterenes (dehydroxylated sterols) from refined rapeseed oil: LC–LC–UV chromatogram (center) with the fractions transferred to GC as numbered in the LC–LC–UV chromatogram. Designation of the sterenes: abbreviated name of the sterol (Sito, sitosterol; Stigma, stigmasterol; Campe, campesterol; Brassica, brassicasterol), number of double bonds (e.g., diene), and molecular structure in numbers referring to the original paper. (Reproduced with permission from Grob K, Biedermann M, Artho A, and Schmid JP (1994) LC, GC, and MS of sterol dehydration products. *Riv. Ital. Sostanze Grasse* 71: 533–538.)

LC columns are usually packed with silica gel or silica derivatized with amino or cyano functions. Online coupling mostly involves 2 mm i.d. columns, compromising between the capacity for matrix material (e.g., edible oil) and the fraction volumes to be transferred. Furthermore, the commonly used flow rates (200–400  $\mu\text{L min}^{-1}$ ) well suit the requirements of transfer into GC, as evaporation rates through an early vapor exit are in the same range. Initially, some applications involved packed fused silica capillary LC columns with fraction volumes in the order of 5–10  $\mu\text{L}$ . However, most applications presuppose higher capacities for the sample matrix.

The mobile phase is usually based on pentane or hexane, containing modifiers, such as dichloromethane, methyl *tert.* methyl ether, or alcohols. Pentane is important because of its easy purification, the absence of oxidation products, and the ease of transfer to GC. Also, polar solvents can be used as long as they are free of water.

Size exclusion chromatography (SEC) with columns of  $\sim 3$  mm i.d. was used for the isolation of pesticides from edible oils or fatty food extracts. Reversed-phase LC with water-containing eluents was used with various (special) transfer techniques, but has probably never been used for routine applications. Water causes several problems, attack of deactivated surfaces being the most severe.

## LC Equipment

**Figure 3** schematically shows an LC–GC instrument as marketed by Fisons/Thermo Electron in the 1990s (Dualchrom 3000). LC equipment optimized for LC–GC differs from conventional LC instruments in several respects. The frequent use of pentane (bp 36°C)

**Figure 3** LC–GC instrument: autosampler, two syringe pumps (main pump and slave pump), LC-switching box with injection valve, valve with first LC column and backflush loop (filled from pressurized bottle, not shown), second LC column on heart cutting valve, LC detector (mostly UV), transfer valve directing to waste or into GC, on-column injector or other inlet device, precolumn (coated or uncoated) ending on T-piece directing to solvent vapor exit or separation column.

mixed with polar modifiers (often with even lower azeotropic boiling points) and the need for accurate flow rates in the order of  $100\text{--}500\ \mu\text{l min}^{-1}$  are the main reasons why syringe pumps are preferable. Often two pumps are used.

For most applications, the LC column (or the first of two columns) is backflushed with a stronger solvent after every sample in order to remove the matrix material. This presupposes a backflush valve of eight ports and a pressurized flask supplying flushing solvent to the backflush loop.

Preseparation with two LC columns presupposes at least one more switching valve enabling heart cutting. This valve is also used for multitransfer applications (several fractions of an LC run transferred to GC), switching the LC column to two plugs while waiting for the end of the GC analysis. Hence LC usually involves three valves.

Dedicated software supports rather sophisticated techniques. For instance, ‘peak detection’ enables adjustment of the time for transfer to GC to signals recorded by the LC detector, thus compensating for shifts in retention times.

## Techniques for Online Transfer to GC

The methods for transferring LC fractions to GC were developed hand in hand with large-volume GC injection. They mostly involved on-column techniques, since these show best performance and follow rather simple rules. The main drawback, the sensitivity to nonevaporating by-products, is not important, since efficient preseparation by LC is also efficient in removing the ‘contaminants’. The principal alternative, programmed temperature vaporizing (PTV) injection in solvent split mode, has rarely been applied.

Techniques enabling the transfer of typically  $200\text{--}1000\ \mu\text{l}$  fractions into GC primarily deal with selective solvent evaporation and the reconcentration of the solutes of interest to sharp initial bands.

### Band Broadening in Time/Space

In GC, two types of broadening of initial bands are distinguished, because they fundamentally differ in their characteristics and the techniques used for their reconcentration.

Band broadening in time is the result of slow introduction of a gaseous sample or of sample vapors into the column: for all solutes, bands have the same width in terms of time, because the first material has the same lead over the last in terms of chromatographic migration time. A band is considered to be sharp

if it is narrow compared to the width of the final peak. If a peak is, e.g., 5 s wide, the initial band should be no broader than 2 s, i.e., the solute material must start the separation process during not more than 2 s. If the column flow rate is, e.g.,  $2\ \text{ml min}^{-1}$ ,  $\sim 50\ \mu\text{l}$  of gas or vapor can enter the column during this time (a  $500\ \mu\text{l}$  fraction in pentane forms some  $150\,000\ \mu\text{l}$  of vapor, dilution with carrier gas not being considered!). Band broadening in time is the problem concerning the volatile components, i.e., those eluted between the column temperature during sample introduction and up to several tens of degrees above it.

Band broadening in space is the result of sample entering the GC system in the liquid phase: the liquid flows into the column until it is spread as a more or less stable layer. All solutes are dispersed over the whole length of the so-called ‘flooded zone’. The initial band should be narrow (short) compared to the terminal bandwidth (length), i.e., the length of the column over which a solute is distributed when leaving into the detector. For 15 and 50 m separation columns, initial band lengths of about 15 and 30 cm, respectively, can be tolerated, but flooded zones often reach 10 m. Band broadening in space is a problem of components eluted at least a few tens of degrees above the column temperature during transfer.

### Reconcentration of Bands Broadened in Time: Cold Trapping, Solvent Effects, Packed Beds (Traps)

Reconcentration of bands broadened in time requires that the first solute material entering the system is hindered in its gas chromatographic migration until the last one entered, i.e., a temporary increase of the retention power.

To achieve cold trapping, the whole column, or just an inlet section, is cooled below the elution temperature of the component(s) of interest as long as sample introduction lasts. Afterwards the temperature is increased to start the chromatographic process. Cooling the column below the elution temperature by  $100^\circ\text{C}$  results in reconcentration by a factor of about 100. Cooling is, however, limited by the dew point of the solvent/carrier gas mixture: lower temperatures cause flooding, and also solvent trapping.

A temporary increase of the retention power can also be achieved by condensed sample solvent acting as a stationary phase. There are two solvent effects: solvent trapping takes place in the flooded column inlet and describes the fact that the solutes are usually released only at the end of solvent evaporation. The elegance of this method is the automatic decay of the retention power at the end of solvent

evaporation. Phase soaking describes the result of co-chromatography of the solute material with the strongly overloading solvent peak in the coated column beyond the flooded zone.

A bed of highly retentive packing material can be used, e.g., in a PTV injector. After completion of sample introduction, this retentive power must be overcome by heating the bed to a high temperature.

### Reconcentration of Bands Broadened in Space: Retention Gap

Solute material spread into the GC separation column by the flow of liquid can be reconcentrated by placing the flooded zone into an uncoated (but deactivated) precolumn. This precolumn represents a zone of low retention power ('retention gap'): the solute material moves through it at a low temperature and is accumulated in the inlet of the separation column because the temperature is still too low to enable noticeable chromatographic migration. The uncoated precolumn must be at least as long as the flooded zone. The retention gap technique shortens initial bands by a factor of 100–1000, enabling the acceptance of flooded zones as long as 50 m.

### Concurrent Eluent Evaporation

(Fully) concurrent eluent evaporation means the liquid (i.e., the solvent) is evaporated during its introduction, i.e., no sample liquid accumulates in the inlet. Basically unlimited volumes of liquid can be introduced in this way (although bands are increasingly broadened in time as introduction lasts longer). However, concurrent solvent evaporation also means that there is no solvent trapping to retain volatile components, i.e., these are lost through the vapor exit together with the solvent vapors or form broad peaks. Hence, the application of concurrent eluent evaporation is restricted to the analysis of components eluted at column temperatures above 120–180°C, depending on the solvent, the volume transferred, and the GC conditions.

To achieve solvent evaporation rates suitable for LC at flow rates of 200–400  $\mu\text{L min}^{-1}$ , vapors must be discharged at a rate of 50–300  $\text{mL min}^{-1}$ . This presupposes a solvent vapor exit (SVE) between the precolumn (sometimes consisting of two pieces, mostly of 0.53 mm i.d.) and the separation column. The SVE is fully open during solvent evaporation and switched to a strong restriction to achieve a small purge flow during analysis.

Concurrent eluent evaporation is most commonly performed with the loop-type interface (Figure 4): the liquid is pushed into the oven-thermostatted precolumn by the carrier gas and stopped there by its

**Figure 4** Design of the loop-type interface. Easy to use for large fraction volumes, but not suitable for components eluted less than 50–80°C above the column temperature during transfer. (Reproduced with permission from Grob K (2000) Efficiency through combining HPLC and HRGC: progress 1995–1999. *Journal of Chromatography A* 892: 407–420.)

own vapor pressure. This requires a GC oven temperature above the solvent boiling point at the inlet pressure. The sample is loaded into a loop with a volume corresponding to the fraction to be transferred, mounted in the transfer switching valve. The carrier gas is supplied from a separate valve (mounted on the same actuator), either pushing the sample liquid into GC or directly entering GC and backflushing the transfer valve. The solvent vapors are usually released through an early vapor exit installed after an uncoated and a retaining (coated) precolumn of 2–3 m each. The uncoated precolumn is used for the reconcentration of solutes spread by the moving liquid, and the retaining precolumn is used for the retention of solutes while solvent vapors are released.

Alternatively, the fraction is pushed by the LC pump into a 5–10 cm fused silica capillary containing a piece of wire and heated to 250–350°C ('wire interface'). The vapors escape through a retaining precolumn of some 3 m  $\times$  0.32 mm i.d. The oven temperature must again be above the solvent boiling point.

The loop-type and the wire interface stop the carrier gas flow during sample introduction; the solvent vapors are discharged through their expansion ('overflow system'). Alternatively, the fraction is introduced into a gas stream ('gas discharge'), usually by a transfer line entering the column through an on-column injector (on-column interface, see below).

Since the vapors are diluted with carrier gas, this permits lower oven temperatures. Performance for volatile solutes is improved, but the suitable oven temperature is more difficult to predict. The vapors are released through a 50 cm  $\times$  0.53 mm i.d. retaining precolumn.

### Retention Gap Technique

If more volatile solutes are to be analyzed (components eluted after the solvent peak), solvent trapping in a flooded precolumn is needed to retain these, i.e., not all solvent can be evaporated concurrently with the introduction. This means that an increasing amount of solvent accumulates during transfer and produces an extending flooded zone. An uncoated precolumn of sufficient capacity to retain the liquid, typically of 5–10 m  $\times$  0.53 mm i.d., is used upstream of the solvent vapor exit (see Figure 5). With the high gas flow rates obtained through an open vapor exit, a 10 m  $\times$  0.53 mm i.d. precolumn safely retains 250  $\mu$ l of (wetting) liquid. A corresponding volume of eluent can be transferred if concurrent solvent evaporation is negligible. If 80–90% of the solvent evaporates during introduction (partially concurrent eluent evaporation), 5–10 times larger fractions are amenable to GC (1250–2500  $\mu$ l).

The on-column interface centers on an on-column injector. Instead of a syringe needle, a thin fused

silica transfer line is permanently installed. The LC fraction is driven by the LC pump and passes through a switching valve (transfer valve), directing the eluent either to waste or into the inlet of the uncoated precolumn. The carrier gas enters from the side (on-column injector) and discharges the solvent vapors, which is the prerequisite for solvent evaporation at the rear of the flooded zone and solvent trapping. The vapor exit is closed shortly before solvent evaporation is completed in order to retain volatile solutes within the system.

### Introduction

The direct analysis of nonvolatile and polymeric organic samples, which may be complex mixtures of natural or synthetic origin, is compromised by virtue of their intractability. Various degradation methods have been developed and pyrolysis, in which a sample is subjected to a short burst of intense heat that initiates thermal fragmentation and the production of a range of smaller molecules, was one of the earliest of these. The pyrolysis products may be separated, identified, and quantified by chromatographic or spectroscopic means (analytical pyrolysis) to provide a characteristic profile of the sample. When the analysis is undertaken by gas chromatography (GC) directly integrated with the pyrolysis system, the technique is known as pyrolysis-gas chromatography (Py-GC). Typically, the sample – which may be a pure or formulated synthetic polymer, a biological matrix such as whole microorganisms, soil or organic geochemical components, or specimens from various origins for forensic analysis – is loaded into the pyrolyzer. Ideally, very small (microgram) amounts of sample are loaded onto a wire or filament, which is then rapidly heated to a temperature range that fragments the macromolecular components into smaller, volatile compounds – usually, 600–800°C. These pyrolysis products are then immediately swept onto the column of a gas chromatograph for separation, detection, and quantification to yield the pyrolysis chromatogram (pyrogram). The GC eluate may be further analyzed by mass spectrometry (MS) to provide reliable identification of the components – a technique known as Py-GC–MS. The pyrogram may be used to provide qualitative information on the identity or composition of the sample or quantitative data on its constitution, or else it may allow mechanistic and kinetic studies of thermal decomposition and fragmentation to be undertaken. A typical polymer pyrogram is shown in **Figure 1**.

The analysis of rubber, which yielded isoprene and dipentene, was the first reported application of analytical pyrolysis (1860). Accessible MS (1948) widened the utility of the technique, which developed into integrated pyrolysis-mass spectrometry (Py-MS, 1953). Pyrolysis with gas chromatographic analysis

(1953) sought to overcome the deficiencies of contemporary MS by using the newly described GC technique (1952) and was rapidly succeeded by fully integrated Py-GC (1959). Py-GC with offline MS soon followed (1961) and combined Py-GC–MS was introduced in 1966. This was further extended (1976) to yield a fully automated system that was so compact and efficient that it could operate on the surface of Mars as part of the Viking program in the search for life on that planet.

### Principles of Pyrolysis-GC

Py-GC is a relatively simple procedure, but there are many processes that must be controlled to yield an effective analysis:

- Sample handling: selection of a representative portion, preparation, and loading into the pyrolyzer in a reproducible way.
- Pyrolysis: delivery of a precisely controlled thermal profile to the sample to initiate reproducible degradation into smaller fragments.
- Transference: migration of pyrolysis products from pyrolyzer to GC without loss or further reaction.
- Separation: efficient separation and elution of the pyrolysis products to provide peaks comprising single components.
- Detection: detection of all significant components in the mixture to allow a reproducible profile to be obtained.
- Quantification: measurement of the peak areas, and perhaps the use of calibration data, to allow effective analysis of the data.
- Identification: reliable confirmation of the structure of the pyrolysis fragments to enable rational assignment of the origins of the products.
- Data handling: mathematical or statistical analysis of quantitative data to provide reliable comparisons and conclusions.

For productive Py-GC analyses to be undertaken, consideration and control of these stages, particularly sample preparation, pyrolysis, and transfer, is necessary and much of the development of the technique has been aimed at defining and minimizing the sources of variation. Although much has been made of the potential for variability in Py-GC, the technique is simple to install and, in many cases, reliable results may be obtained without problems. As sample complexity increases and results are to be exchanged

**Figure 1** Pyrogram of natural rubber (polyisoprene) at 750°C, showing the monomer (isoprene), dimer (dipentene), trimers, and tetramers.

between various centers, control becomes more important. This control is now discussed in more detail.

## Pyrolysis

### Pyrolysis Temperature

When sufficient heat is supplied to a sample, a series of primary bond fissions result that yield the primary pyrolysis fragments. These reactions are likely to have different activation energies and, thus, the product distribution (and hence the pyrogram) is dependent upon the temperature of pyrolysis. Smaller, less characteristic fragments are frequently favored at higher pyrolysis temperatures. To ensure reproducible pyrograms, it is essential that a precisely controlled pyrolysis temperature is used. This is often described as the final pyrolysis temperature but is more properly referred to as the equilibrium temperature ( $T_{eq}$ ). The control of this parameter alone, however, is not sufficient to guarantee reproducible pyrolysis. The fact that the product distribution is highly sensitive to temperature means that the heating rate, too, may exert a profound effect on the appearance of a pyrogram. This is because pyrolysis reactions occur very rapidly, so that substantial, or total, degradation may occur while the

sample is being heated to  $T_{eq}$ . Reactions may thus occur nonisothermally during heating, with or without a subsequent isothermal phase. The temperature dependence of pyrolysis reactions ensures that analyses undertaken using heating regimes that accentuate such nonisothermal conditions are likely to be subject to much variation. A precisely defined temperature–time profile (TTP) is an essential component of pyrolyzer design; the temperature rise time (TRT) should be small and values of 8 ms or less are now possible.

Additionally, variability in the total heating time (THT) may result in variable volatilization of fragments from the pyrolyzer to the analyzer and high, uncontrolled temperatures may also cause secondary pyrolysis of the primary fragments. Again, such processes endanger reproducibility. For similar reasons, the cooling of the pyrolyzer unit after removal of the energy source should be as rapid as possible. Units with low thermal mass minimize secondary pyrolysis and evaporation during the cooling stage. A half-square-wave heating profile (rapid heating to  $T_{eq}$ —precise duration of heat—rapid cooling) is ideal for pyrolysis performance, with heating and cooling as rapid as possible so that the time during which the sample is subjected to  $T_{eq}$  is close to the THT. The pyrolyzer must also be interfaced with the analytical

device so that the loss of volatile samples is reduced to a minimum with no opportunities for adsorptive loss, condensation, or secondary reaction. In Py-GC, pyrolysis should be as close to the column as possible.

### Sample Handling

The temperature dependence of pyrolysis pathways implies that reproducible fragmentation requires that the entire sample experiences the same heating profile. Ideally, the temperature of the sample should follow that of the pyrolyzer probe, a situation that is best achieved with intimate contact between the sample and the filament. Very thin samples, near the center of the pyrolysis filament (to avoid cooler end regions), are advised. This also minimizes temperature gradients throughout the depth of the sample. In contrast, thicker films allow the primary pyrolysis products, which are produced close to the surface of the pyrolysis wire, to diffuse through non-degraded sample before escaping to the analyzer. At the high temperatures involved, uncontrolled, competitive secondary reactions that will compromise pyrogram reproducibility may occur. Samples should preferably be within the 5–50  $\mu\text{g}$  range for optimum results and deposited directly on to the heated wire or conductor. For soluble compounds, a known volume of solution in a volatile solvent may be used for quantitative transfer to the filament as a thin, uniform film. Greater care is necessary with insoluble samples, firstly to ensure that a thin uniform film is obtained – perhaps by deposition on to a rotating wire – and to ensure that the sample is homogeneous or representative of the bulk. Solvent must be totally removed prior to pyrolysis. Heated-filament systems allow gentle preheating for this purpose. The pyrolysis filament should also be scrupulously clean: heating in a moist hydrogen atmosphere for ferromagnetic conductors or prefiring filament systems have been recommended.

### Instrumentation

Instrument development has concentrated on the control of TRT,  $T_{\text{eq}}$ , and THT while enabling small samples to be handled easily. Although some specialized pyrolysis units, such as high- or low-energy laser, dielectric discharge, infrared, and photolytic systems and those suitable for liquids, have been reported, most workers have used pyrolyzers that are based upon furnace heating, inductive heating, or a resistively heated filament; each may be designed to ensure adequate performance, so that final temperatures with relative standard deviations of <1% are obtainable.

### Furnace Pyrolyzers

Furnace systems were the first to be used in pyrolysis and usually involve the sample being dropped or pushed into the preheated pyrolysis zone. Such units have been widely described but have a low reputation for reproducibility. This is largely due to the poor control of the heating profile and the large sample sizes that have been used. The pyrolyzer design has often favored secondary reactions, although in some instances (e.g., the mechanism of tobacco pyrolysis) this may be of advantage. A vertical design, however, is outstanding in its performance. The sample ( $\sim 50 \mu\text{g}$ ) is held in a platinum bucket, which is suspended above the heating zone so that no thermal reactions can occur. When the bucket is released, the sample falls into the heated zone to initiate a rapid pyrolysis. Volatile products are rapidly swept away from the heated zone by the carrier gas; to minimize secondary products the low-dead-volume unit progressively narrows to increase carrier gas flow rates. This system may also be modified to provide two independent heating zones (Figure 2). At first the sample is held in an upper chamber at 300°C to desorb volatiles such as plasticizers, giving a desorption chromatogram, followed by pyrolysis at 550°C in the lower chamber to generate the pyrogram.

### Curie-Point Pyrolyzers

A ferromagnetic sample-holder is placed in a radio-frequency (RF) oscillator ( $\sim 500 \text{ kHz}$  to 1.2 MHz). This induces an alternating magnetic flux in the conductor and hysteresis losses and eddy currents cause a rapid increase in temperature. Heating continues until the Curie point of the material is reached, when a transition from ferromagnetism to paramagnetism occurs, energy input to the sample holder falls, and the temperature is held constant. This Curie-point temperature is a function of the specific alloy used, so the pyrolysis temperature is not continuously variable but a range of values may be obtained by adjusting the composition of the conductor:

Temperature (°C)	Composition	
	%Ni/%Fe	%Ni/%Co
400	45/55	
510	49.4/50.6	
590	60/40	
700		67/33
770	0/100	
800		55/45
900		40/60
1128		0/100

**Figure 2** Two-stage high-performance vertical microfurnace pyrolyzer: A, sample holder unit; B, thermal desorption oven, 50–400°C; C, pyrolyzer oven, 100–800°C; D, Py-GC interface, 50–400°C; E, O-ring; F, sample holder chuck; G, sample cup; H, carrier gas; I, GC column; K, pole; L, cylinder; M, air-purging nut. (Diagram kindly supplied by Professor Tsuge S, Nagoya University, Japan as described in Watanabe C, Teraishi K, Tsuge S, Ohtani H, and Hashimoto K (1991) *Journal of High Resolution Chromatography* 14: 269–272.)

This system offers the choice of sample holder shape (wire, filament, boat, tube, folded foil) and the lack of electrical contact between the power supply and the conductor, which facilitates automation. Conductors are frequently enclosed within quartz tubes, which collect nonvolatile products (Figure 3).

In practice, the temperature control of Curie-point pyrolyzers is dependent upon features such as the power of the RF generator and the geometry of the sample holder. With low-power units (~30 W), TRTs of 500 ms to 600°C and 1.35 s to 700°C are typical with the Curie point never being reached, while high-power units (2 kW at 1.1 MHz) give better heating (20–30 ms to 700°C) but may overshoot the Curie point. Different RF frequencies require different-diameter wires for optimal performance while the shape of the conductor, and its position within the induction coil, may significantly affect the heating profile; even small variations in alloy composition cause deviations in pyrolysis temperature.

**Figure 3** High-powered Curie-point pyrolyzer: 1, glass pyrolysis injector with stainless steel needle; 2, ferromagnetic wire; 3, Teflon carrier gas tubing; 4, impulse cable; 5, induction coil; 6, aluminum housing; 7, adaptor for fastening; 8, GC inlet; 9, GC septum; 10, GC column; 11, carrier gas changeover valve. (Reproduced from Fischer Labor- und Verfahrenstechnik, Meckenheim bei Bonn, Germany.)

Further, it is not possible to vary the pyrolysis temperature readily. Stepped pyrolyses, in which the same sample is repetitively subjected to a series of increasing temperatures, are not possible, and a good description of the thermal profile of the sample holder is generally not available. However, they are used frequently; they are robust and convenient to operate; and they allow a series of samples to be loaded onto the conductors and queued for analysis.

### Heated-Filament Pyrolyzers

With resistively heated-filament pyrolyzers, the sample is placed on a ribbon that is heated by the passage of an electric current. Fixed voltages provide poor control. With low voltages very long TRTs (10–30 s) result, whereas at higher voltages TRTs are decreased

( $\sim 1$  s) but very high temperatures that might melt the conductor may be generated. Better performance is provided by boosted heating systems in which an initial surge of power, provided by a high current or a capacitor-discharge system, heats the filament rapidly. Power to the conductor is reduced to a maintenance current when  $T_{eq}$  is reached. A highly refined system that uses a capacitor discharge is the Pyroprobe<sup>®</sup> (CDS analytical, Oxford, PA, USA) in which a platinum pyrolysis filament may operate as the sample holder, the heating element, and the temperature sensor. The increase in resistance of the filament with temperature is monitored to provide feedback to a computer that controls the filament voltage. The system is capable of controlled variable heating rates ( $20^{\circ}\text{C ms}^{-1}$  to  $0.01^{\circ}\text{C min}^{-1}$ ) giving declared TRTs of 8 ms to  $600^{\circ}\text{C}$  and 17 ms to  $1000^{\circ}\text{C}$ . The pyrolysis temperature may be set from ambient up to  $1400^{\circ}\text{C}$  at  $1^{\circ}\text{C}$  intervals and variation in pyrolysis time from 0.01 s to 1000 min is also possible. Various probes are available to facilitate sampling handling and include the pyrolysis of samples held in quartz boats. In contrast, the Pyrola<sup>®</sup> system (Pyrolab, Lund, Sweden) uses two sequential half-square-wave voltage pulses. The first is high enough to heat the Pt-filament to the expected pyrolysis temperature (up to  $1400^{\circ}\text{C}$ ) and short enough ( $\text{TRT} \leq 8$  ms) to minimize secondary effects. The second current pulse compensates for cooling effects. An optic cable transmits the light from the middle of the filament to a photodiode in the control unit. In this way the TTP can be displayed on the PC. This system is unique in that the TTP can be measured and printed. The pyrolysis temperature is also measured by the resistance of the Pt-filament, which is needed, since the photodiode is not sensitive at temperatures lower than about  $600^{\circ}\text{C}$ . A removable glass cell is surrounding the Pt-filament in order to let the light pass to the optic cable and to let the nonvolatile pyrolysis products condense to protect the GC-MS.

It is essential in mechanistic work to exert precise control over the pyrolysis temperature. However, quoted temperatures may be average values over the whole filament. A pyrolysis unit that uses a refined feedback system was developed at the University of Birmingham to overcome this problem (Figure 4). The filament temperature is measured near its central point by means of a very fine thermocouple spot-welded to the rear of the filament. The thermocouple output is compared to that of a reference voltage preset to correspond to the required  $T_{eq}$ . A large current ( $\sim 40$  A) drives a temperature increase and, as the two voltages converge, the filament current is reduced rapidly to a maintenance level. TRTs of 50 ms to  $800 \pm 0.5^{\circ}\text{C}$  were obtained with 15 ms to

**Figure 4** Advanced boosted heated-filament pyrolyzer with thermocouple feedback. The chromel–alumel thermocouple wires ( $d$ ,  $25\ \mu\text{m}$ ) attached to the nichrome ribbon have a small thermal capacity with a fast response time. When mounted on the GC, the chamber is surrounded by a heater jacket. (Reproduced with permission from Lehrle RS, Robb JC, and Suggate R (1982) *European Polymer Journal* 18: 443–461; © Elsevier.)

$500^{\circ}\text{C}$  achievable with less-robust filaments. Cooling periods are the limiting factor in producing the ideal square-wave thermal profile.

Resistively heated-filament pyrolyzers offer the most versatility of the available units. They allow a wide range of programmed temperature and time profiles including stepped pyrolysis. This allows the elucidation of the thermal stability profile of the sample; it provides data to allow the kinetic analysis of polymer degradation and may facilitate the identification of unknown samples.

### Laser Pyrolyzers

Pyrolysis by laser has involved both high- and low-powered systems, with the former, in general, giving smaller, less-characteristic molecular fragments. The specialized nature of the technique has limited the applications of this pyrolysis mode. However, a relatively cheap system has now been designed that

**Figure 5** Convenient low-power laser pyrolysis system: A, injection needle; B, stainless steel body; Cu, copper cylinder; FL, flash lamp; G, gas; H, heater; HS, heated sensor; I, injector; K, pyrolysis chamber; LB, laser beam; M<sub>1</sub>, HR mirror; M<sub>2</sub>, output mirror; N, Nd-GGG medium; OF, optical fiber; OR, O-ring; P, probe; PC, pumping chamber; PS, power supply; QC, quartz capillary; S, sample; Sh, shield; Sw, Swagelok; T, trigger; V, voltage supply. (Reproduced with permission from Cecchetti W, Polloni R, Bergamasco G, *et al.* (1992) *Journal of Analytical and Applied Pyrolysis* 23: 165–173; © Elsevier.)

simplifies and improves access to laser pyrolysis. This system uses an Nd–Cr–GGG laser that delivers 600 mJ pulses of 500  $\mu$ s with repeats at 40 s intervals. No cooling is necessary due to the slow repeat rate and the laser energy is delivered to the pyrolysis chamber via an optical fiber (Figure 5).

## Pyrolysis-GC

### The Integrated System

Pyrolyzers are interfaced with standard gas chromatographs by inserting the pyrolysis unit into the GC carrier gas upstream of the column inlet, and the products are swept directly onto the column for analysis. Connections should minimize dead volume and the presence of cold spots that may result in component loss, peak broadening, lack of resolution, and insensitivity (Figure 6). Capillary columns can separate small amounts of product and they provide high resolution, which allows separation of many of the products from complex samples, and are used routinely, generally with split ratios of 50–100:1. To compensate for dead volume while allowing the analysis of small samples, cryogenic focusing has been employed. This allows on-column trapping of the pyrolysate, using a liquid nitrogen trap, prior to analysis and allows better resolution and more sensitive detection. The development of tarry deposits on the top of a capillary column reduces efficiency;

these should be eliminated by removing the affected inlet of the column or by back-flushing.

Early Py-GC analyses used flame ionization detectors. These are sensitive and respond quantitatively over a wide range of sample loadings, but for some components this may prove insensitive. For such compounds, and to provide reliable identification of eluted components, MS is generally employed (Py-GC–MS), with electron impact and chemical ionization being readily available. Py-GC–MS also provides a powerful data-handling ability where stored spectra may be reconstituted to provide mass pyrograms, mass spectra of individual components or removal of background contamination, or to monitor uniquely specific fragments.

### Automation

Pyrolyzers have been adapted to provide automatic, unattended control of Py-GC. An early system used precoated pyrolysis wires held in quartz tubes on a turntable. These were sequentially loaded, accurately positioned in the induction coil, pyrolyzed, analyzed by capillary GC, and ejected. An alternative has used an automatic solids injector for samples enclosed in iron foil, and a furnace system has enabled sampling of the Martian surface. Autosampling systems based upon conventional pyrolyzers are now commercially available for resistively heated filaments, microfurnaces, and Curie-point pyrolyzers. One such system

**Figure 6** Heated interface for Py-GC. Sample material is placed directly onto the platinum filament, which is inserted into the glass cell of the interface. The injection needle passes through the injection port of the GC to the column inlet. (Diagram kindly supplied by Dr I. Ericsson, Pyrolab, Lund, Sweden.)

(CDS Analytical, USA) uses an autosampler with a carousel to hold 36 quartz tubes for sequential analysis (Figure 7). The tubes are dropped into a stabilized platinum coil for pyrolysis, where air is purged from the system before connection to the GC. Another automated filament system (Pyrolab, Sweden) uses either 6 or 14 probes (Figure 6). Different pyrolysis methods like isothermal, sequential, fractionated pyrolysis, and pyrolysis can be chosen individually for each probe. In another design (Japan Analytical Industry Co., Japan) samples enclosed in inductive foil are loaded into a 20-compartment magazine. This is flushed with carrier gas and then a sample is dropped into the induction coil for pyrolysis. Exhausted samples are retrieved magnetically and are retained in a cool storage compartment. An auto-sampling microfurnace system (Frontier Laboratories LTD, Japan) uses a tray that holds up to 48 deactivated stainless steel sample cups.

## Data Handling

Appropriate data handling is essential to the successful application of Py-GC techniques. This is particularly so when fingerprint comparisons are to be made using standard pyrograms to identify unknown samples. In forensic applications, taxonomy or other areas of classification, where complex pyrograms are obtained, a detailed statistical analysis, using

multivariate methods such as cluster analysis, non-linear mapping, and factor analysis may be required. In contrast, in studies concerned with the mechanistic and kinetic aspects of polymer degradation, relatively few primary products may be observed and it is sufficient to be able to identify and quantify these, perhaps by the use of Py-GC-MS. In general, the same integration routines employed in the analysis of peaks found in chromatograms of routine GC applications may be applied in the analysis of pyrolysis chromatograms.

## Scaling of Pyrograms

The use of Py-GC to characterize unknown specimens by comparing a pyrogram from an unidentified sample with that of a standard is a common application. If such a comparison is to be made on the basis of peak area intensities rather than by the presence of unique components, care must be taken to ensure that variations in sample loading do not compromise the analysis. Rescaling the peak areas may be achieved simply by normalizing all peaks to the intensity of the largest peak in the pyrogram, as indicated in eqn [1] in Table 1. However, some peaks in the pyrogram are intrinsically more variable than others and this simple procedure may threaten reliable transformation if normalization is applied to such a peak. To minimize intensity differences, the

**Figure 7** Automated resistively heated filament pyrolysis using quartz sample tubes, front view, and side view of the pyrolysis chamber. 1, Quartz tubes; 2, sample carousel; 3, optical sensor for locating tubes; 4, funnel to guide tubes into inlet valve; 5, inlet valve; 6, quartz chamber; 7, heating filament; 8, outlet valve; 9, GC online valve; 10, connection to GC injector.

use of the fractional total area (intensity) for each peak, as indicated by eqn [2] (Table 1), is preferred.

Problems may be also encountered in obtaining precise retention times over extended periods of analysis. This may lead to difficulties in the assignment of corresponding peaks within different pyrograms, particularly if many components are present. When the intensities of such peaks are to be compared for identification purposes, normalization of retention times may be undertaken. This procedure uses standard components, which may be present naturally in the pyrogram and are readily identified as such, or are added as internal or external markers. This allows the calculation of a time-rescaled pyrogram, from the retention times of the standard components, according to eqn [3] (Table 1).

### Fingerprint Comparisons

Except in the simplest of cases, it is unusual for all peaks within a pyrogram to be used in the analysis, and hence the matter of peak selection must be addressed. It is sensible to select the most intense peaks within the pyrogram for this purpose, but two other aspects should be considered. These are the within

(intra)-sample and the between (inter)-sample variations. The within-sample variation measures the reproducibility of the pyrogram and highly variable peaks could be eliminated from the analysis. However, those peaks that have a high between-sample variation are most useful in assigning identity. Care needs to be taken that weak or variable peaks, which may be highly diagnostic, are not eliminated from the dataset. Typically, three peaks may be sufficient for simple synthetic polymer samples, while for taxonomic applications 13–24 or even up to 100 may be used. Various techniques have been used to assess the degree of correspondence between pyrograms; these are summarized in Table 1 (eqns [4]–[10]). To compare pyrograms that have only subtle differences, more complex chemometric methods should be chosen. The nonlinear mapping technique, which uses a two-dimensional representation of differences between pyrograms, has shown particular promise in taxonomic applications using pyrolysis data.

### Applications

Py-GC is widely used in the analysis of complex, insoluble, and nonvolatile samples and applications are

many and varied. Some of these are illustrated with examples from the major fields of application.

### Synthetic Polymers

Typical pyrolysis reactions of addition polymers are illustrated in Figure 8 and involve:

- Depolymerization or unzipping (Figure 8A), which results in successive free-radical eliminations of the monomer, often accompanied by intramolecular rearrangement to generate dimers and trimers. This behavior is typical of polystyrene and polymethacrylates.
- Side-group elimination (Figure 8A), which involves loss of pendant groups on the polymer backbone to form a polyene. Further reaction involves scission, aromatization, and char formation. Typical is the case of PVC, which eliminates HCl followed by backbiting to form benzene, toluene, naphthalene, and other aromatics.
- Random chain scission (Figure 8C), which occurs in polymers such as polyethylene with the formation of a free radical. This initiates C–C bond scission with the formation of an olefin and a terminal free radical. The latter may abstract hydrogen from the chain to produce a methyl terminus. Random repetition of these processes gives a homologous series of alkane, -alkene, and  $\alpha,\omega$ -diene.

In addition to empirical fingerprint comparisons, for which library data are available and which are more usual in taxonomic and forensic work, these reactions may be used to study various aspects of polymer structure and properties.

### Analysis of Composition

Mixtures, formulated blends, or copolymers usually provide distinctive pyrolysis fragments that enable qualitative and quantitative analysis of the components to be undertaken, e.g., natural rubber (isoprene, dipentene), butadiene rubber (butadiene, vinylcyclohexene), styrene–butadiene rubber (butadiene, vinylcyclohexene, styrene). Pyrolyses are performed at a temperature that maximizes the production of a characteristic fragment, perhaps following stepped pyrolysis for unknown samples, and components are quantified by comparison with a calibration graph from pure standards. Different yields of products from mixed homopolymers and from copolymers of similar constitution may be found owing to different thermal stabilities. Appropriate copolymers should thus be used as standards and mass balance should be assessed to allow for nonvolatile additives. The amount of polymer within a matrix (e.g., ~0.5%

styrene–butadiene on filter paper) may also be readily quantified without extraction.

### Determination of Structure

Detailed information concerning the microstructure of polymers may be obtained using high-resolution Py-GC; block and random copolymers may be distinguished and sequence lengths may be investigated. Poly(chloropropylene) undergoes degradation by side-chain stripping (Figure 8B) and the preferred head-to-tail component produces 1,3,5-trimethylbenzene. Small amounts of head-to-head sequences generate the 1,2,4-isomer. The random chain scission of polyolefins, particularly when combined with hydrogenation, provides information on the stereoregularity.

For example, the reduced  $C_{11}$ ,  $C_{12}$ , and  $C_{13}$  fragments of polypropylene appear as doublets due to two geometrical isomers that originate from the syndiotactic or isotactic disposition of the pendant methyl groups. Similar analyses provide details on branching due to the clusters of isomeric peaks. Product distribution is also dependent upon molecular mass. Figure 9 records pyrograms from poly(2,6-dimethyl-1,4-phenylene ether), which yields a range of phenolic products due to Fries rearrangements. End-group analysis using specific fragments correlated well with  $^{13}\text{C}$  NMR values.

### Mechanisms of Thermal Degradation

Product distribution, variable or stepped pyrolysis and kinetic studies have all been used to expose mechanistic events during polymer degradation. For example, the thermal degradation of polystyrene has been elucidated using the block copolymer poly(styrene-*b*-styrene- $d_8$ ). Hybrid and homo monomers (styrene) and dimers (2,4-diphenylbut-1-ene) were detected but without hybrid trimers (2,4,6-triphenylhex-1-ene) (Figure 10). The amount of hybrid dimer far exceeds that which might arise from adjacent residues, while similar proportions of dimers were obtained when the two homopolymers were pyrolyzed together. Data indicate intermolecular reaction rather than the previously proposed 1,3-transfer.

Kinetic parameters may be determined by pyrolyzing samples for various periods of time and measuring the extent of degradation. For example, if a pyrolysis time  $t$  yields a component peak of area  $A$ , and an extended pyrolysis period, allowing complete degradation, gives an area  $A_\infty$ , the rate constant for a first-order degradation ( $k_{\text{obs}}$ ) may be obtained from eqn [11] using a series of pyrolysis times:

$$-\ln(1 - A_t/A_\infty) = k_{\text{obs}}t \quad [11]$$

**Table 1** Expressions used in the quantitative description of pyrolysis data

Value	Equation	Parameters	Comments
Normalized intensity	$I_i^n = \frac{100I_i}{I_{100\%}}$	[1] $I_i^n$ = intensity (%) of the normalized peak $I_i$ = intensity of peak before normalization $I_{100\%}$ = intensity of the largest peak in the pyrogram	Re-scales peak intensities to largest in pyrogram: ideally, this should be of low variability
Fractional intensity	$I_i^n = \frac{I_i}{\sum_{j=1}^N I_j}$	[2] $I_i^n$ = fractional intensity of a normalized peak $i$ of initial intensity $I_i$ $I_j$ = intensities of the $N$ selected peaks in the pyrogram	Re-scales intensities as a fraction of total intensity: reduces problem of highly variable peaks used for normalization
Corrected retention time	$t_B^s = t_A^s + \frac{(t_B^r - t_A^r)(t_C^s - t_A^s)}{t_C^r - t_A^r}$	[3] $t_B^s$ = rescaled retention time of component B, occurring between the two standards A and C Subscripts A, B, C indicate three species (A, B, C); superscripts r ( $t^r$ ) indicate retention times in the original program; superscripts s ( $t^s$ ) indicate retention times in the standardized pyrogram	Standardizes retention times to those of standard components eluting before and after the peak of interest. Compensates for variable retention times in pyrogram
Similarity value	$S_{i,j}^v = \frac{100N_c}{N_c + N_u}$	[4] $S_{i,j}^v$ = similarity value between pyrogram ( $i$ ) and pyrogram ( $j$ ) $N_c$ = number of peaks common to both pyrograms $N_u$ = number of unique peaks in both pyrograms	Simple comparison of two pyrograms. A value of $S_{i,j}^v = 100$ indicates a perfect match
Dissimilarity index	$d_{i,j} = 100 \sum_{k=1}^N \frac{ R_i^k - R_j^k }{(N^2 - I)/2}$	[5] $d_{i,j}$ = dissimilarity index between pyrogram ( $i$ ) and pyrogram ( $j$ ) $R_i^k$ = rank order of the $k$ th peak in pyrogram ( $i$ ) $R_j^k$ = rank order of the $k$ th peak in pyrogram ( $j$ ) $N$ = number of peaks in each pyrogram $I$ = 0 when $N$ is even; 1 when $N$ is odd	Compares the intensity rank order of corresponding peaks in each pyrogram. A value of $d_{i,j} = 0$ indicates a perfect match
Similarity coefficient	$S_{i,j} = \frac{\sum_{k=1}^N \left( \frac{I_i^k}{I_j^k} \right)}{N}$	[6] $S_{i,j}$ = similarity coefficient between pyrogram ( $i$ ) and pyrogram ( $j$ ) $I_i^k$ = normalized intensity of the $k$ th peak in pyrogram ( $i$ ) $I_j^k$ = corresponding intensity in pyrogram ( $j$ ) The quotient is arranged such that the more intense peak is the denominator ( $I_j^k > I_i^k$ ) $N$ = number of unique peaks in the programs	A value of 1.0 signifies a perfect match. Values in excess of 0.84, based upon an analysis of 13–15 peaks selected from the overall pyrogram, have provided an acceptable degree of similarity for microorganisms

Euclidean distance	$D_{i,j} = \left( \sum_{k=1}^N (I_i^k - I_j^k)^2 \right)^{1/2} \quad [7]$	<p><math>D_{i,j}</math> = the Euclidean distance between pyrogram (<math>i</math>) and pyrogram (<math>j</math>)</p> <p><math>I_i^k</math> = intensity of the <math>k</math>th peak in pyrogram (<math>i</math>)</p> <p><math>I_j^k</math> = intensity of the <math>k</math>th peak in pyrogram (<math>j</math>)</p> <p><math>N</math> = number of peaks in each pyrogram (dimensionality)</p>	<p>Calculates the dissimilarity between two pyrograms by assessing the difference as a distance in <math>N</math>-dimensional space</p> <p>Weighting functions enhance the utility of this approach</p>
FIT factor	$F_{i,j} = 10001 - \frac{\sum_{k=1}^N (I_i^k - I_j^k)^2}{\sum_{k=1}^N ((I_i^k)^2 + (I_j^k)^2)} \quad [8]$	<p><math>F_{i,j}</math> is the FIT factor between pyrograms (<math>i</math>) and (<math>j</math>)</p> <p><math>I_i^k</math> = intensity of the <math>k</math>th peak in pyrogram (<math>i</math>)</p> <p><math>I_j^k</math> = corresponding intensity in pyrogram (<math>j</math>)</p> <p><math>N</math> = number of peaks selected from each pyrogram</p>	<p>A perfect match is indicated by <math>F_{i,j} = 1000</math></p>
Matching coefficient	$M_{i,j} = 100 \sum_{j=1}^N \left( 1 - \frac{I_i^L - I_j^U}{I_i^L + I_j^U} \right) \quad [9]$	<p><math>M_{i,j}</math> = matching coefficient between pyrograms (<math>i</math>) and (<math>j</math>)</p> <p><math>I_i^L</math> = intensities of the peaks in the library spectra</p> <p><math>I_j^U</math> = intensities of the corresponding peaks in the unknown spectrum</p> <p><math>N</math> = number of peaks in the library pyrogram</p>	<p>Proposed for the fingerprint comparison of unknown samples with pyrograms held in a library</p> <p>A perfect match is indicated by <math>M_{i,j} = 100</math></p>
Probability of error	$P_{n,m}^N = \frac{(n - N)!}{n!m!} \quad [10]$	<p><math>P_{n,m}^N</math> = probability of two samples being considered identical when they are not</p> <p><math>n</math> = number of strips along abscissa (temperature)</p> <p><math>m</math> = number of strips up ordinate (intensity %)</p> <p><math>N</math> = number of peaks compared and matching in two pyrograms</p>	<p><math>m</math> and <math>n</math> are determined by the reproducibility of intensity and temperature measurements and are <math>\pm 3\sigma</math> (standard deviation <math>\sigma_1, \sigma_T</math>) wide</p> <p><math>m = 100/6\sigma_1 (\approx 5)</math></p> <p><math>n = (T_2 - T_1)/6\sigma_T (\approx 25-30)</math></p>

**Figure 10** Pyrograms of (A) polystyrene and (B) poly(styrene-*b*-styrene- $d_8$ ) at 500°C, dimer intensities 14:45:41%. (Reproduced with permission from Ohtani H, Yuyama T, Tsuge S, Plage B, and Schulten H-R (1990) *European Polymer Journal* 26: 893–899; © Elsevier.)

The areas may be obtained by subjecting a single sample to a series of pyrolyses at a fixed temperature. This enables the cumulative degradation versus time to be obtained, but aggregated errors and thermal

conditioning are possible problems. A better method involves heating each of a series of samples twice only. The initial pyrolysis, for a period  $t$  that yields  $A_t$ , is followed by a second pyrolysis that completes

the degradation and generates an area  $A$  such that  $A_{\infty} = A_t + A$ . Alternatively, a series of replicate samples may be subjected to increasing pyrolysis times sufficient to give a series of  $A_t$  values and  $A_{\infty}$ .

Kinetic schemes for the degradation of various polymers may be derived. For example, depolymerization involves chain end ( $k_i$ ) or random scission ( $k'_i$ ) initiation; monomer depropagation ( $k_d$ ); and complete unzipping, first- ( $k'_t$ ) or second- ( $k_t$ ) order termination, with the observed rate constant being related to the degree of polymerization ( $D_0$ ). Thus, for a first-order termination reaction, the observed rate constant is as follows:

Chain-end initiation:  $k_{\text{obs}}$  versus  $1/D_0$  is linear through the origin (eqn [12]):

$$k_{\text{obs}} = \frac{k_d k_i}{k'_t D_0} \quad [12]$$

Random scission initiation:  $k_{\text{obs}}$  versus  $D_0$  is constant (eqn [13]):

$$k_{\text{obs}} = \frac{2k'_i k_d}{k'_t} \quad [13]$$

A mixture of chain-end and random scission initiation:  $k_{\text{obs}}$  versus  $1/D_0$  is linear but not through the origin (eqn [14]):

$$k_{\text{obs}} = \frac{k_i k_d}{D_0 k'_t} + \frac{2k'_i k_d}{k'_t} \quad [14]$$

## Forensic Science

Forensic aspects are largely concerned with the fingerprint identification of samples (paint, fibers, adhesives) that may connect a suspect with the scene of a crime. Emphasis has been placed upon the reliability of comparisons and considerable data are available. Paint samples are especially important in automobile accidents and may be thermosetting alkyds (e.g., polyesters and glycerol), thermoplastic acrylics (e.g., poly(methyl methacrylate)), and thermosetting acrylics (e.g., styrene-acrylate copolymers). Each may be distinguished, and paints from different years, manufacturers, and even models may often be identified. For example, a characteristic component of alkyd resins is phthalic anhydride; other peaks include styrene modifications (styrene), toluene modifications (vinyl toluene), urethane modifications (toluene diisocyanate), epoxy esters (phenol), together with aliphatic residues (acrolein, methacrolein) and propenol (from glycerol or pentaerythritol). Related interests are concerned with the identification of paints and lacquers used in art, particularly to identify forgeries. For example, Figure 11 records pyrograms from cyclohexanone-formaldehyde resins used as varnishes.

**Figure 11** Pyrolysis of cyclohexanone-formaldehyde resins at 650°C for 5 s showing differences due to source and ageing. Identified peaks are: 1 = cyclohexene; 3 = cyclohexanone; 4 = 2-methylcyclohexanone; 5 = 2-methylenecyclohexanone; 8 = 2-methyl-6-methylenecyclohexanone; 9 = 2,6-dimethylenecyclohexanone; peaks 22–44 correspond to products with two or three cyclohexane residues. (From Mestdagh H, Rolando C, and Sablier M (1992) *Analytical Chemistry* 64: 2221–2226.)

Characteristic pyrograms are obtained from Laropal K100, Resin N, and an aged sample of Resin N sufficient to discriminate between them. Documents may be assayed for the identity of toner materials in photocopies, inks, coatings, and the adhesives used on labels. Other forensic investigations involve tapes used in the fabrication of bombs or to bind victims.

The technique is also proving useful in archaeology where, for example, charred food remains have been characterized, showing clear chemical differences in their origin; and it has been used to show that external encrustation (patina) on supposedly authentic ancient Egyptian vessels (Thutmosis III, 1475–1425 BC) was identical (i.e., artificially added) and was similar to that produced by fatty acid salts. Samples of amber have been studied, both to discriminate between authentic and forged materials and to help locate the geographic origin of a particular sample.

### Taxonomy

Pyrolysis has found widespread application in the identification of microorganisms, although detailed data handling is often necessary. In particular, the technique offers a standard analytical procedure for a wide range of samples that can be completed in a much shorter time than a battery of morphological, biochemical, and serological tests. Pyrograms from microorganisms reflect the pyrolysis of the major groups of biochemicals – proteins (e.g., characterized by elimination, yielding nitriles, and side-chain stripping to give benzene, pyrrole, and indole derivatives), carbohydrates (e.g., dehydration to furan and pyran derivatives), and lipids (e.g., elimination, scission, and decarboxylation to fatty acids, esters, acrolein, and homologous olefins and paraffins). In addition to pyrolysis control, culture of the microorganisms and the collection of a representative sample, free from medium, also require standardization. Over 200 components are usually produced and high-resolution Py-GC is essential.

Pyrograms usually display the same products in different relative yields but, in some cases, unique fragments occur. These may readily be investigated using mass fragmentography. For example, streptococci have been distinguished by the presence of a unique component (possibly derived from glucitol phosphate), monitored exclusively at  $m/z$  86, due to a specific antigen. Additionally, some microorganisms produce poly( $\beta$ -hydroxy-butyrate), a biodegradable polymer now gaining acceptance in drug delivery. This polymer yields *trans*-2-butenic acid, together with smaller amounts of the *cis*-isomer and 3-butenic acid, which serves as a reliable marker for Legionellaceae and Bacilli on pyrolysis. In contrast, Enterobacteriaceae showed low levels of this compound, which, coincidentally, also appears at  $m/z$  86, but at much shorter retention times. More typical is the characterization of *Ascomycetes* (yeasts) where 28 strains from 13 genera could be distinguished, on the basis of many qualitative and quantitative differences, using 14 peaks, within 49 h. This compares favorably with conventional analyses, which require 7–10 days. An alternative procedure for the identification of microorganisms has used the profile of fatty acids volatilized as the methyl esters. An extension of Py-GC involves on-column methylation of whole organisms and GC analysis of the resultant fatty acid methyl esters. The utility of this simple and rapid procedure is compared, in Figure 12, with standard extraction and derivatization. Py-GC has also been used to identify more complex samples. For example, winter wheat cultivars (*Triticum aestivum*) may be distinguished by pattern-recognition techniques, but seasonal growth conditions were as important as variety in determining pyrogram variability.

**Figure 12** Fatty acid methyl ester profiles from *Escherichia coli* by (A) Py-GC with trimethylanilinium hydroxide at 500°C for 10 s and (B) extraction and derivatization. Major peaks are: 4,  $C_{14:0}$ ; 11,  $C_{16:0}$ ; 14, cyclopropyl- $C_{17}$ ; 17,  $C_{18:1}$ ; 20, isopropyl- $C_{19}$ . ### Organic Geopolymers

It is estimated that there are some  $6 \times 10^{14}$  tons of organic matter in the earth's crust, the bulk of which is in Phanerozoic (<570 million years old) sedimentary rocks. Terrestrial organic polymers are of interest in the characterization, assessment, and maturation processes that result in the conversion of vegetation into humic substances and fossil fuels. Intractable, condensed aromatic structures, which may be present in low amounts, contribute to the structure of these substances and Py-GC dramatically extends the analytical options. The polysaccharide and lignified components of cells, boosted by the products of microbial activity, contribute strongly to the composition of the organic matter, with lignins providing abundant phenolic derivatives in the pyrograms of partially decayed humus. Various soil horizons, separated into fractions, provide characteristic oxygen- and nitrogen-containing components derived from biomacromolecules and over 300 have been described. Products such as homologous fatty acids, residues from proteins, polysaccharides, and lignin allow samples to be characterized and classified. The analysis of kerogen and petroleum source rock may be undertaken in a similar way and pyrograms from such samples are characterized by high yields of hydrocarbons. Samples range from hydrogen-rich types that yield low-mass linear paraffins and olefins, to the hydrogen-depleted fractions based on

condensed hydrocarbons that yield many aromatic products. Sequential pyrolysis also provides information on distribution and maturation. Almost 150 compounds have been identified from kerogen samples, including those from lignin, lipid, and condensed origin. Principal components analysis on 37 of these components allows prediction of the source rock hydrogen index (HI<sub>0</sub>) from a single Py-GC analysis. The rank of coals may also be assessed by Py-GC, for example, by studying the oxygen functionalization of monocyclic derivatives, while the formation of a series of long-chain *n*-alkanes is indicative of a thermoplastic coal. Pyrograms from coal macerals (which are petrological unit of a geological sample) consist mainly of alkylbenzenes, alkyl-naphthalenes, alkylphenols, alk-1-enes, and alkanes with quantitative differences depending upon precursor material and maturation. The development of life-detection systems for extraterrestrial exploration has also depended upon organic geochemical analysis. Even desert sands show abundant evidence of biomacromolecules and pyrograms are characterized by olefins, nitriles, benzenes, phenols, indoles, and furans. The lack of any such compounds from Lunar and Martian samples indicates their lifelessness.

## Limitations

Although the applications described here have concerned diverse macromolecular samples, pyrolysis is also of utility in the analysis of smaller molecules, particularly quaternary ammonium compounds, which undergo quantitative thermal fragmentation to volatile products. For example, the specificity and sensitivity afforded by Py-GC/MS with mass fragmentography renders the technique suitable for the analysis of endogenous neurotransmitters such as acetylcholine at the 1–2 pmol level. However, in all cases, analytical throughput is limited by the retention times of the pyrolysis products, a condition that is particularly severe in taxonomic applications. Automation allows extended use, but direct Py-MS

offers substantial reductions in analytical time, although a single pyrolysis product may give rise to several ions, a single ion may be derived from several pyrolysis products, and identical  $M^{+•}$  values result from isomers that may be resolved by Py-GC. Direct Py-MS also allows detection of larger or more polar pyrolysis products that are unlikely to be efficiently chromatographed. This may provide a substantial increase in structural information for complex samples of biological origin.

## Introduction

Many techniques have been described for the detection of compounds separated by gas chromatography.

Space limitations, however, allow only those detectors that are widely used and have reached commercial maturity to be discussed in this article. The important spectroscopic detectors (e.g., mass and infrared spectrometry) used for structure elucidation as well as detection are discussed in separate articles.

The principal methods of detection can be categorized as ionization, bulk physical property, optical, and

condensed hydrocarbons that yield many aromatic products. Sequential pyrolysis also provides information on distribution and maturation. Almost 150 compounds have been identified from kerogen samples, including those from lignin, lipid, and condensed origin. Principal components analysis on 37 of these components allows prediction of the source rock hydrogen index (HI<sub>0</sub>) from a single Py-GC analysis. The rank of coals may also be assessed by Py-GC, for example, by studying the oxygen functionalization of monocyclic derivatives, while the formation of a series of long-chain *n*-alkanes is indicative of a thermoplastic coal. Pyrograms from coal macerals (which are petrological unit of a geological sample) consist mainly of alkylbenzenes, alkyl-naphthalenes, alkylphenols, alk-1-enes, and alkanes with quantitative differences depending upon precursor material and maturation.
